The PaIntE model of intonation
Antje Schweitzer, Bernd Möbius, Gregor Möhler, and Grzegorz Dogil

1 Introduction

The PaIntE model (Möhler and Conkie, 1998; Möhler, 2001) was originally developed for F0 modeling in text-to-speech (TTS) synthesis. Its purpose was to generate F0 contours that are as close to natural, human-produced F0 contours as possible. We will show in this chapter that it can also be used for more general research on intonation. The PaIntE model assumes that only the F0 contour in the vicinity of so-called intonation events contributes to the intonational meaning of an utterance, whereas the stretches in between these events arise from interpolation and do not affect the overall meaning. This view is manifested in the model’s name, Parameterized Intonation Events, or PaIntE for short.

PaIntE can be classified as a sequential model of intonation, in that it composes the F0 contour from a sequence of local contours, each associated with some kind of meaningful tonal event, and that these events or local contours do not interact, or affect each other. PaInte shares this view with the well-known, phonologically motivated, Tone Sequence Model (TSM, Pierrehumbert, 1980) for instance. The sequential approach is also popular in speech synthesis, with the Tilt model (Taylor, 1998) as probably the most wide-spread example.

While the PaIntE model has long been successfully used to generate perceptually appropriate F0 contours in speech synthesis, we will show in this chapter that PaIntE is also well suited for intonation research beyond speech synthesis.

To this end we will introduce the PaIntE model in some detail in section 2, focussing on several aspects: First, we will show that PaIntE shares assumptions with autosegmental models of intonation (section 2.1). Second, in contrast to many other models, which aim to identify typical shapes that correspond to intonation categories, PaIntE assumes that several dimensions contribute to the meaning of tonal events, and quantifies these dimensions by continuous parameters. The
overall shape of the event is then determined by these parameters, as illustrated in some detail in section 2.2. Next, we will provide more information on how the PaIntE parameters can be derived from a database (section 2.3), or how they can be predicted for speech synthesis (section 2.4).

In section 3 we will illustrate that the PaIntE intonation events can be related to categories posited by autosegmental approaches to intonation. Also, as we will show in section 4, PaIntE can be used for answering typical questions in intonation research. To this end we will discuss some recent studies that have used the PaIntE model to investigate intonation, some from an autosegmental perspective, and some from an exemplar-theoretic perspective. Thus sections 3 and 4 show that PaIntE is compatible with an autosegmental approach to intonation, but can also serve an exemplar-theoretic approach. Its flexibility lies in the fact that on the one hand, it can take autosegmental categories into account, and that the PaIntE parameters can be linked to these categories. On the other hand however it does not necessarily assume that such categories exist. We discuss the advantages of this property of PaIntE in section 5 and offer some conclusions in section 6.

2 The PaIntE model and its parameters

To motivate the requirements and objectives of an F0 model in the context of speech synthesis, we briefly sketch the role of such a model in the TTS synthesis process. We will then consider the commonalities between intonation models for synthesis and more general models of intonation from a theoretical point of view, before turning to the specific implementation of PaIntE in terms of its parameters, and how these parameters can be extracted for analysis, or predicted for synthesis.

2.1 Intonation models and speech synthesis

Traditional concatenative TTS systems generate speech starting out from a given, text-only, specification of the utterance to be synthesized. This specification is passed through a pipeline of mostly independent modules, each of which incrementally adds linguistic, phonological, and phonetic information. Towards the end of this process, an F0 model adds concrete F0 values to the specification, and at the end of the pipeline, synthesized speech is generated by concatenating speech segments from a recorded database and, if necessary, manipulating these segments to match the F0 values that the F0 model has predicted.
What F0 models for synthesis and more general intonation models have in common, at the very least, is that they are interested in relating aspects of meaning to tonal contours. For instance, a TTS system might want to relate sentence-internal major syntactic phrase boundaries to rising intonation contours, and sentence-final syntactic phrase boundaries to falling contours. Or it may relate exponents of information structure to contours conveying the intended meaning.

Many concatenative TTS systems treat the problem of predicting F0 contours following what may be called a phonological approach. According to Ladd (1996, p. 11), a phonological model of intonation has to minimally consist of two ingredients: first, a finite set of intonation categories, and second, a mapping from these categories to continuous acoustic parameters. In this vein, many TTS systems take into account linguistic properties inferred from the text to first predict the occurrence of a finite set of intonation categories such as pitch accents or bounday tones, and then generate concrete F0 values in a second step. In fact, in the context of TTS the term F0 model often refers just to this second step, i.e. the generation of an F0 contour given a specification that already contains the desired location of some kind of intonation categories in the utterance.

In the case of a phonological approach to the TTS problem as outlined above, an additional commonality between F0 models for synthesis and more general intonation models is that both types of models have to address two issues: (i) identify the relevant categories and (ii) specify how these categories are implemented phonetically in terms of F0 (and, realistically, in terms of other prosodic cues such as duration).

A TTS system which follows such a phonological approach has the additional objective to specify a mapping from linguistic properties to intonation categories. This is not necessarily an objective of a more general model of intonation. However, in order to establish a distinction between two intonation categories, even a more general model would have to show that exchanging the two categories in some utterance context changes the meaning of the utterance. Therefore a more general intonation model cannot be entirely silent regarding the relation between meaning and intonation categories. The exact nature of this relation is still an open issue. For instance, there is consensus that in West-Germanic languages such as English and German,

\footnote{This holds under the assumption that establishing intonation categories works analogously to the segmental domain, where segmental categories are motivated by providing minimal pairs of words that differ only in the segmental category and have different meanings.}
information structure affects pitch accent placement (Terken and Hirschberg, 1994; Féry and Kügler, 2008) and even the type of pitch accent (Pierrehumbert and Hirschberg, 1990; Chen et al., 2007). However, to capture this impact, researchers have to refer to fine distinctions in information status that naïve speakers are probably not aware of. Pierrehumbert and Hirschberg (1990), e.g., elaborate differences between five meanings, termed new, addition of new value, accessible, modification of given and given by Baumann et al. (2015), that are claimed to give rise to different pitch accents. However, Baumann and Grice (2006) show that for German a more fine-grained notion of accessibility is needed since accent types differ depending on the way in which the accessible information can be inferred from the text. Similarly, Baumann et al. (2015) differentiate 10 classes of information status which differ in accentedness and type. A crucial difference then is that a TTS system can only rely on more coarse-grained meaning that can be estimated from raw text, viz. text without annotation or markup, because this is what serves as input to a TTS system. Even worse, the TTS system has to expect that the estimated meaning may be incorrect at times.

Given these difficulties, most TTS systems treat the mapping from linguistic properties to intonation categories as a separate task, which is addressed as part of the linguistic analysis of the text to be synthesized (Sproat, 1998; Taylor, 2009). Then the task of the F0 model is “only” to map from a specification of the utterance which already includes intonation categories to concrete intonation contours. In other terms, the task of the F0 model in synthesis is to provide the phonetic implementation of phonological categories that have been determined in a preceding linguistic analysis step. This separate treatment is fostered by the dissemination of speech corpora with manually annotated ToBI labels (e.g., Ostendorf et al., 1996; Rapp, 1998; Calhoun et al., 2010; Eckart et al., 2012), which conveniently serve as training and testing data for this second step in F0 modeling.

Arguably, the separate treatment may also reflect a split in research approaches between studies that relate meaning to intonation categories (e.g., Beckman, 1996; Büring, 1997; Féry, 1993; Pierrehumbert and Hirschberg, 1990, among many others) and studies that investigate phonetic detail in the implementation of F0 contours (e.g., Pierrehumbert, 1981; Kohler, 1990; Ladd et al., 2000; van Santen and Möbius, 2000, among many others).

The PaIntE model follows the practice of separating the prediction of categories from the actual F0 modeling. It does not necessarily state what the exact nature of the categories is—all that is said is that they
are “intonation events”, and the core task of the PaIntE model then is to generate concrete F0 contours that implement these intonation events. However, PaIntE acknowledges that ToBI categories are an obvious and convenient choice in that respect, and provides means to take ToBI categories as the relevant intonation events for which local F0 contours have to be generated, by way of a configuration parameter. Before we go into detail on how the PaIntE parameters of a given contour can be extracted, and how the parameters can be predicted in speech synthesis, we will first discuss how they determine the concrete F0 shapes.

2.2 The PaIntE parameters

All intonation models dedicated to F0 modeling for speech synthesis parameterize the F0 contour in some way. In case of PaIntE, the shape of the F0 contour around local intonation events is captured by six linguistically motivated parameters. Together they determine the F0 contour in a window of up to three syllables centered around the event. In the original implementation the events were taken to be pitch accents and boundary tones posited by a German ToBI variant (Mayer, 1995), i.e. the PaIntE parameters served to specify the exact shape of the F0 contour on and around pitch accents and boundary tones. The global contour then arises by interpolation between these events.

Mathematically PaIntE employs a function of time, with \( f(x) \) giving the F0 values at time \( x \). It is defined as follows:

\[
f(x) = d - \frac{c_1}{1 + e^{-a_1(b-x)}} - \frac{c_2}{1 + e^{-a_2(x-b)}}
\]

This function yields a peak shape (Figure 1), where the first term, the \( d \) constant, gives the upper bound. We will see below that \( d \) can be interpreted as peak height parameter. From this \( d \) constant, two sigmoids are subtracted, the second and third terms in the equation. The first of these two sigmoids alone would result in a falling shape, starting at zero in negative infinity (\( \lim_{x \to -\infty} = 0 \)) and ending at infinity (\( \lim_{x \to \infty} = -c_1 \)). The most pronounced part of this fall starts approximately at the value for parameter \( b \). Since this sigmoid is subtracted from the \( d \) constant, this effectively yields a rise towards \( d \), i.e. towards the peak height parameter. The amplitude of this rise is \( c_1 \), and the pronounced part of the rise ends approximately at the value for parameter \( b \). In the same way, subtracting the second, originally rising, sigmoid adds a fall component to this rising shape. The pronounced part of the fall starts close to parameter \( b \), i.e. approximately at the
point where the first sigmoid levels off. Thus we get a pronounced peak with the peak location affected by the $b$ parameter; in other words, $b$ can be interpreted as the peak alignment parameter. As parameter $d$ is the upper bound for rise and fall, and thus the upper bound for the peak, this parameter corresponds to peak height. The amplitudes of the rising and falling parts are determined by parameters (rise amplitude) and (fall amplitude), and their steepness by parameters (steepness of rise) and (steepness of fall).

Figure 1: Example PaIntE contour in a window of three syllables around a pitch-accented syllable ($\sigma^*$). See text for more details.

PaIntE provides several methods to normalize the time axis. In the standard variant, which is called sylnorm normalization, the time axis inside the approximation window is normalized such that syllable boundaries occur at integer values, with the syllable related to the intonation event beginning at 0 and ending at 1. In the sylnorm case, $b$ determines the temporal alignment of the peak in terms of relative position within the syllables in the approximation window. A hypothetical example peak contour for a syllable associated with a pitch accent, using sylnorm normalization, is given in Figure 1. The PaIntE function as specified in equation (1) above is indicated by the solid line. Syllable boundaries are indicated by vertical lines, the
syllables themselves are indicated by σ symbols, and the pitch-accented syllable is marked as σ*. The location of the b parameter (peak alignment) is marked by the bold vertical line; parameters (rise amplitude) and (fall amplitude) are indicated by the arrows, and the d parameter (peak height) by the dashed tick at the y-axis. Parameters (steepness of rise) and (steepness of fall) cannot be read off the graphical representation in the same way as the other parameters, but they are hinted at in Figure 1.

The shape with the pronounced peak is not prototypical for all syllables that are associated with some intonation event. Often, we observe just a falling or just a rising contour, without a clear peak. To accommodate such cases when parameterizing existing F0 contours, the PaIntE model first tries to detect a peak in the three-syllable window. It uses the PaIntE function as specified in (1) only in case there is a peak. If no peak is detected, the function is used with only the first sigmoid for rising contours or only the second sigmoid in case of falling contours, yielding the following two functions.

\[ f_{\text{rise}}(x) = d - \frac{c_1}{1 + e^{-a_1(b - x) + g}} \]  
(2)

\[ f_{\text{fall}}(x) = d - \frac{c_2}{1 + e^{-a_2|x - b| + g}} \]  
(3)

We have indicated these alternative functions by dashed lines in Figure 1. They are partly hidden by the PaIntE function (solid line), but it can be seen that the b parameter, indicated by the bold vertical line, does indeed occur at the point where the dashed line for the rising sigmoid starts to level off, and where the fall in the dashed line for the falling sigmoid is about to become more pronounced. It is thus a reasonable estimate of the end of the rise, given that mathematically the rise does not end at all because it never reaches d before infinity. Similarly the fall effectively starts in (negative) infinity, not somewhere in the window depicted here. The same argument can be made for parameter d—it is only an estimate for the height of F0 at the end of the rise, or the beginning of the fall, respectively, and is never really reached. However, it can be seen in Figure 1 that for the two example sigmoids the difference between d and the function values at the edges of the three-syllable window is not detectable by eye: the dashed line for the falling sigmoid seems to reach the y-axis exactly where the tick for d is located.
It should also be noted here that in the case of the “full” PaIntE function with the peak as given in (1), the $b$ parameter is again only an approximation of the temporal alignment of the peak in the syllable structure: it can be seen in Figure 1 that the peak’s exact temporal location, as indicated by the dotted line, is actually a small distance to the right of the $b$ parameter itself, which is indicated by the bold vertical line. The exact displacement depends on the values of the $a$, $c$, and $e$ parameters. In this specific example for instance, the true peak is 0.04 units to the right of the $b$ value, i.e., if the last syllable in this example were 200 ms long, $b$ as an approximation of the temporal alignment of the peak would be off by 8 ms. If a better estimate of the peak alignment is desired, one can resort to sampling the curve specified by the PaIntE function and finding the point where the maximum sample occurs.

To get an impression of the accuracy of $b$ for approximating the location of the peak covering a representative number of contexts, we have estimated both $b$ and the true temporal alignment of the peak for approx. 17,000 syllables in a database of 2 hours of speech which had been approximated using the full PaIntE function in (1). The mean absolute error in syllable units was approx. 0.052, and the median 0.039. In absolute time, this corresponded to a mean absolute error of approx. 10 ms, and a median of approx. 8 ms. Since the time resolution in deriving $F_0$ from the speech signal is usually in this order, we consider the approximation to be exact enough. However, if necessary, it is easy to estimate the true location of the peak given the six PaIntE parameters as suggested here.

The same point can be made for the $d$ parameter (peak height). In the example in Figure 1 the $d$ parameter is 199 Hz, while the true peak height is at approx. 197.3 Hz. For the 17,000 syllables from our database, the mean absolute error was approx. 1.380 Hz, and the median absolute error was approx. 1.167 Hz. This is in the order of the just noticeable difference of approx. 1 Hz in human perception of complex tones at pitch levels below 500 Hz (Kollmeier et al., 2008). This leads us to conclude that the approximation is accurate enough for almost all purposes. If a higher accuracy is needed, we again recommend estimating the true peak height numerically by sampling.

So far we have only discussed the application of PaIntE using the sylnorm normalization, however PaIntE also provides an alternative called anchor_norm normalization. In this case, each syllable is split

---

2 There is no closed-form expression for the true location of $b$, so the peak location must be approximated using numerical methods.
into three parts representing the (unvoiced) onset of the syllable, its sonorant nucleus, which is defined as containing the nucleus and possibly preceding voiced consonants in the onset, and, finally, the coda. This normalization is motivated by findings that indicate that timing in F0 movements is relative to syllable structure (House, 1996, 1997; van Santen and Möbius, 2000). Using anchor_norm normalization, each syllable in the approximation window is again normalized to length one with the same values for syllable boundaries as in the sylnorm case. Syllable-internally, the unvoiced onset is adjusted linearly to a length of 30% of the syllable duration. The sonorant nucleus then spans another 50%, i.e. it ranges from 30% to 80% of the syllable duration, and the coda finally goes from 80% to 100% of the syllable duration.

It should be noted that the approximation window may in fact be shorter than three syllables depending on the context. This is the case if silence intervals intervene between the syllables. Also, as stated above, PaIntE can be configured to take information regarding prosodic categories associated with the syllables into account. In this case, the window does not extend to neighboring syllables that also carry a pitch accent, or across syllable boundaries that are associated with a phrase boundary. Reducing the approximation window in these cases is motivated by the fact that speakers before boundaries compress tonal contours that in another context would extend into the following syllables (Mayer, 1995; Grabe, 1998; Jilka et al., 1999). Similarly, in cases where it is known that a syllable is associated with a pitch accent that exhibits a late peak (e.g. in an L*H accent as assumed by Mayer (1995)), the approximation window does not contain the preceding syllable. However, it is possible to configure PaIntE to enforce the three-syllable window in all contexts, just as it is possible to parameterize every single syllable in cases where no prosodic annotation is available that indicate where intonation events are expected.

2.3 Extracting the PaIntE parameters

Before the PaIntE parameters of a given F0 contour can be approximated, the raw F0 contour is smoothed in order to eliminate microprosodic effects and outliers. To this end, PaIntE uses the smooth_f0 algorithm provided with the Edinburgh Speech Tools (Taylor et al., 1999). smooth_f0 is a median smoother which interpolates across unvoiced regions, but not across silences.
In preparing the approximation, PaIntE then first looks for an F0 peak in the smoothed contour in the middle of the approximation window, as well as local minima to the right and left of the maximum. The locations of the maximum and the minima, as well as the number of frames available, are used to determine which of three approximation methods is appropriate in that particular context:

- **Mean F0 approximation.** No PaIntE approximation takes place if there are less than two voiced frames for the current window or if the two minima are less than 5 frames apart. In these cases, PaIntE reverts to a simple approximation called meanf0 by just determining the mean F0 value in that window as the $d$ parameter ($peak height$); the five other PaIntE parameters are set to 0.

- **Single sigmoid approximation.** If either the left or the right minimum coincide with the maximum, i.e., a rise or fall have been detected, but not a clear peak, the PaIntE approximation is modified to leave out one of the two sigmoids, as described above in section 2.2. Depending on which sigmoid is left out, this is called the rise sigmoid or the fall sigmoid method. In this case, the $a$ parameter ($steepness of rise or fall$) of the missing sigmoid is set to -1, and its $c$ parameter ($rise or fall amplitude$) is set to 0. The remaining parameters are determined by the single sigmoid approximation.

- **PaIntE approximation.** In the standard case, in which a peak has been detected, i.e. neither minimum coincides with the maximum, the approximation is carried out using the PaIntE function as defined in equation (1) above. This is called the $pfun$ method.

The approximation itself determines the PaIntE parameters using the appropriate functions listed above, choosing the parameters so that the root mean squared error (RMSE) between actual F0 values and the corresponding values in the PaIntE function is minimized. Finding the optimal combination of parameters is an optimization problem, and PaIntE uses a conjugate gradient method to arrive at a local optimum.

### 2.4 Predicting the PaIntE parameters

There are several ways in which the PaIntE parameters can be used to generate F0 contours in speech synthesis. As discussed above, speech synthesis systems often approach predicting F0 contours as a two-step problem, in which first a set of intonation categories, for instance, the ToBI categories, is predicted from text. As a result, one would have a
specification of the utterance to be synthesized which already includes concrete ToBI categories. The task of F0 modeling can then be viewed as mapping from the ToBI category to the PaIntE parameters, taking linguistic and phonological context into account.

Typically, this mapping would be learned using machine learning techniques on a database that is annotated with all the context properties that will be available at synthesis time, and with the category labels. Most machine learning schemes predict only one parameter at a time, thus, one approach would be to train six models, each of which predicts one PaIntE parameter given the context. However, even if each predicted parameter may be plausible, this does not ensure that the combination of the six predicted parameters is plausible, too. One way to avoid this problem is to first determine a finite number of “typical” combinations using clustering techniques. For instance, Möhler and Conkie (1998) used vector quantization, experimenting with between 4 and 32 clusters, whereas Möhler (2001) used up to 64 clusters. Then the actual F0 modeling consists of mapping from the given context to one of the clusters instead of to the continuous parameters, thereby turning the regression problem into a classification problem.

The idea of determining a number of typical phonetic implementations by clustering may lead to the question of whether the ToBI categories could be completely replaced by clusters found in this way. However, Möhler (2001) found that the results are better if GToBI(S) categories are taken into account, both in terms of RMSE between synthesized contour and original, and in terms of correlation between the two. This finding is just one indication that there is a correlation between ToBI-like categories and the PaIntE parameters. In the following section we will show that indeed there is a systematic relationship between these categories and the PaIntE parameters, as the parameters reflect properties that are related to the defining characteristics of the ToBI categories.

3 Relating PaIntE to prosodic categories

The PaIntE parameters can be related to established categories in a straightforward way. To demonstrate this we will show here that the PaIntE parameters reflect the expected shape of contours associated with ToBI-style categories, in our case the tonal categories assumed by the German ToBI variant proposed by Mayer (1995). We refer to this variant as German ToBI (Stuttgart variant), or GToBI(S) for short in the following. To this end we will examine PaIntE parameters of pitch-
accented syllables extracted from a large database of German read speech.

The database that we will use for this purpose was recorded for unit selection speech synthesis (Barbisch et al., 2007) in the course of the SmartWeb project (Wahlster, 2004). It was read by a professional male speaker of Standard German and contains typical, isolated utterances of five different genres, usually consisting of one, or at most two, short sentences, corresponding to several prosodic phrases. All utterances were annotated on the segment, syllable, and word level, and prosodically labeled according to GToBI(S). Prosodic labeling for each utterance was carried out by one of three human labelers, supervised and instructed by the first author, in the process of building a database for unit selection speech synthesis. The database amounts to 2 hours of speech, containing 72,000 segments, 28,000 syllables, and 14,000 words.

GToBI(S) assumes five basic types of pitch accents, L*H, H*L, L*HL, HH*L, and H*M, sometimes described as rise, fall, rise-fall, early peak, and stylized contour, respectively. Just like other ToBI approaches it assumes that pitch accents are characterized by either a high, or a low, target associated with the accented syllable, and indicates this association using the “starred tone” notation H* or L*. It also assumes that the contour before and after the starred tones is determined by trailing and leading tones. In contrast to many other ToBI variants the notation for these tones is without a + sign to separate trailing and leading tones from the starred tone, but this is a purely notational difference.

Another, less trivial, difference is that GToBI(S) allows tritonal accents: the L*HL accent has two trailing tones, H and L, and the HH*L accent has both a leading H and a trailing L tone. Also, it assumes that the L*H accent and the H*L accent have slightly less prominent allotonic variants, i.e. alternative realizations that do not change the underlying meaning of the accent: Mayer (1995) suggests that they can be realized by just the starred tone on the accented syllable, and that the trailing tone can be split off and realized later (partial linking), or can even be omitted completely (complete linking). This results in two monotonal accents H* and L*, which are interpreted as variants for the H*L and L*H accents, respectively, which only differ in perceived prominence, but not in meaning. Another important difference to the wide-spread GToBI labeling scheme proposed by Grice and colleagues (Grice and Baumann, 2002; Grice et al., 2005) is that GToBI(S) does not distinguish between an L+H* and an L*+H pitch accent. GToBI(S) provides only the latter category, viz. L*H in
Mayer’s notation. Cases where other GToBI variants assume L+H* are accounted for in other ways, for instance by assuming a monotonal H*, where the low pitch level just before the accented syllable is caused by other factors, for instance by partial linking of a preceding accent.

Apart from this, the expected shape of the pitch contour for each accent is manifested in its notation, as in all ToBI dialects: the contour is expected to reach the target for the starred tone ideally in the middle of the accented syllable, the targets for leading tones on the pre-accented syllable, and the targets for the trailing tones on the post-accented syllable or syllables.
Figure 2: PalIntE contours for some GToBI(S) pitch accents. Dotted lines indicate syllable boundaries, σ symbols represent syllables, the accented syllable is indicated by . Solid vertical lines indicate the peak alignment parameter b, and dashed lines indicate the “true” peak location as estimated using the sampling method outlined above. The type of pitch accent according to manual prosodic annotation is indicated within each panel.

Figure 2 shows parametrization results for 9 pitch-accented syllables selected for illustration from the database described above. We find that the properties expected given the GToBI(S) categories are reflected in the concrete contours, although there are some differences in the detailed implementation. For instance, in the first accent, identified as an L*HL accent, the rise already starts at the beginning of the accented syllable, reaches the peak at the boundary to the following syllable, and falls within the post-accented syllable. It is thus realized in a more compressed way than expected given its description by
Mayer (1995). In the middle panel of the first row, the peak in the H*L accent is at the boundary between the accented and the post-accented syllable, i.e. later than the middle of the accented syllable. In the next three accents, all L*H accents, the rise starts on the accented syllable and continues into the next syllable, reaching the peak early in this syllable (in the right panel in the first row), well within this syllable (in the left-most panel in the middle row), or late in this syllable (middle panel in the middle row). Note that in this last example the contour exhibits a pronounced peak with an abrupt fall, which could be due to a reset to a low pitch level for the next target and thus does not necessarily reflect a property of the L*H accent in question. It should also be noted that the first of these three L*H accents does not exhibit a peak: it was parameterized using the function with only the rising sigmoid.

In the following panel (the right-most panel in the middle row) we can see a prototypical example of a monotonal H* accent, with a less pronounced, broad peak, and relatively low amplitudes, which corresponds well to its characterization as being less prominent than the bitonal H*L variant. Similarly, the three accents in the bottom row reflect the expected properties well: the H*L has a high target in the accented syllable, the L*H rises to a peak at the boundary of the next syllable, and in the HH*L, the contour is already high throughout the preceding syllable and falls to a low level in the post-accented syllable.

To return once more to the question of how accurate the $b$ and $d$ parameters are, we have indicated the “true” values for peak height and peak alignment by dashed lines in all cases where the approximation was carried out using the full PaIntE function. It can be seen that there is no discernible gap between the peak height in the contour and the horizontal line which indicates the “true” peak height. However, the “true” temporal alignment, indicated by the dashed vertical line, is at some distance to the $b$ parameter as specified in the PaIntE function, indicated by the solid vertical line. This is most obvious in the two H*L accents in the top middle panel and in the bottom left panel, as well as in the HH*L accent in the bottom right panel. However, as can be seen in these examples, these larger differences always occur in cases with broader peaks, where one could argue that it is hard to tell where exactly the peak should lie anyway.

The above examples demonstrate that it is possible to find the expected properties of pitch accents reflected in the PaIntE parameterization results. But does this also hold on a larger scale, across many examples? To investigate this question, we will examine density plots of parameters $b$ (peak alignment), $d$ (rise amplitude), $f$ (fall
amplitude), and $d$ (peak height), obtained from the database introduced above. Since GToBI does not make any predictions about the steepness of the contours, we will not discuss parameters (steepness of rise) and (steepness of fall) here. Because of limitations in space we will only address the most frequent of the basic GToBI(S) accents, viz. the L*$H$, H*$L$, and L*$HL$ accents.

![Density plots of the b parameter (peak alignment) for some GToBI(S) accents. Left panel: H*$L$ accents (dashed line) have their peak earlier in the accented syllable than L*$HL$ accents (dot-dashed line). L*$H$ accents (solid line) have their peak either on the accented or on the post-accented syllable. Right panel: The bimodal distribution for L*$H$ accents (solid line, repeated from left panel, different scaling) obviously arises because L*$H$ accents in word-final syllables (dashed line) have their peak on the accented syllable, and L*$H$ accents in word-internal syllables (dot-dashed line) have their peak on the following syllable.]

Figure 3 shows density plots of the $b$ parameter (peak alignment). They are based on parametrization results of the approx. 3,200 syllables with L*$H$ accents, approx. 1,800 syllables with H*$L$ accents, and approx. 270 syllables with L*$HL$ accents in our database. Density plots show how likely a certain range of values is in the underlying data: Peaks appear at values that are more likely to occur for the underlying sample, whereas valleys appear at values that are less likely to occur.

---

3 Also, the HH*$L$ and H*$M$ accents were not frequent enough in our data to reliably estimate their densities.
We again indicate syllable boundaries by vertical lines. Thus the broad peak in the dashed line for $H^*L$ accents in the left panel, between the two vertical lines, indicates that $H^*L$ accents are most likely to have their peak in the middle of the accented syllable. For $L^*HL$ accents, which are indicated by the dot-dashed line, surprisingly, the peak is also on the accented syllable. From the description of $L^*HL$ accents given by Féry (1993, p. 94) and Mayer (1995), one would expect this peak to be on the post-accented syllable in many cases. Nevertheless, compared to $H^*L$ and $H^*$, the peak for $L^*HL$ accents is shifted further towards the syllable boundary. It is also slightly more narrow than the two peaks of the $H^*L$ and $H^*$ distributions, indicating less variation of $b$ for $L^*HL$ accents.

Finally, the density for $L^*H$ accents (solid line) is bimodal: $L^*H$ accents are almost equally likely to have their peak either right before the syllable boundary, just as $L^*HL$ accents did, or in the later part of the post-accented syllable. One might interpret this as evidence for two distinct categories $L^*H^*$ (with the peak on the accented syllable) and $L^*+H$ (with the peak on the post-accented syllable) as in the more wide-spread GToBI variant (Grice and Baumann, 2002; Grice et al., 2005); however, the right panel in Figure 3 shows that this bimodal distribution comes about because $L^*H$ is realized differently on word-final syllables than on non-final syllables. Here, the dashed line represents $L^*H$ accents that occurred on word-final syllables, and the dot-dashed line represents $L^*H$ accents that occurred on word-internal syllables. Obviously, these two contexts cause the bimodal distribution: $L^*H$ accents on word-final syllables almost always have their peak in the accented syllable, while word-internal $L^*H$ accents tend to have their peak on the post-accented syllable. In other words, the tonal movement on $L^*H$ accents usually does not cross word boundaries, instead it is timed to occur earlier before word boundaries.

The example of the alignment parameter $b$ above shows that the PaIntE parameters not only capture well-known properties of the GToBI(S) accents, but that they can also serve to investigate context-dependent aspects of phonetic implementation, as in the case of word-internal vs. word-final $L^*H$ accents above.

\footnote{Thanks to Jörg Mayer for suggesting word finality as a possible explanation for the earlier peak.}
Figure 4: Density plots of the $d$ parameter (peak height) for the most frequent accents and for unaccented syllables. H*L accents (dashed line) exhibit the lowest values for $d$; L*HL accents (dot-dashed line) and L*H accents (solid line) are characterized by higher and more variable values for $d$.

Figure 4 gives density plots for parameter $d$ (peak height). Values for $d$ in Hertz are indicated on the x axis: values to the right indicate higher peaks. Figure 4 thus shows that syllables associated with H*L accents (dashed line) are very likely to exhibit low values for $d$: the peak in the line indicates that values just below 120 Hz for peak height are most probable. Compared to L*H (solid line) and L*HL (dot-dashed line) the peaks of H*L accents are lower. This is due to the prevalence of nuclear, i.e., phrase-final, H*L accents over pre-nuclear H*L accents: 93% of the H*L accents in the database are nuclear accents. For nuclear accents, lower peaks must be expected because of F0 declination, i.e. the global trend of F0 to decline over the course of the utterance (e.g., Cooper and Sorensen, 1981; Gussenhoven and Rietveld, 1988; Pierrehumbert, 1979). Indeed, the density plot for non-nuclear H*L accents (not depicted here) is shifted to the right and broader, similar to the distribution for L*H accents. Peaks of L*HL accents (dot-dashed line) are high even though they are usually nuclear accents in our data (84%). The distribution for L*H accents (solid line) is similar to that of L*HL accents (dot-dashed line), although there is again more variation for L*H accents.
Figure 5: Density plots of the parameter (rise amplitude, left panel) and the parameter (fall amplitude, right panel) for the most frequent accents. H*L accents (dashed line) usually exhibit low and high values; vice versa, L*H accents (solid line) exhibit low and high values. L*HL accents (dot-dashed line) are characterized by high values of both and.

The last two PaIntE parameters to be discussed here, and , determine the amplitude of the rise towards the peak () and the amplitude of the fall after the peak () in Hertz. Figure 5 shows the distributions of (left panel) and (right panel) for different accent types. Looking at H*L accents first, which are indicated by the dashed line, there is little surprise. It is obvious that they tend to have low values of (rise amplitude), but higher values of (fall amplitude): their distribution shows a pronounced peak for values of around 0 to 10 Hertz, and although the distribution extends to the right with values of up to 60 to 80 Hertz, the higher values are much less likely. Their distribution, on the other hand, shows a clear dominance of moderately high values with values of around 0 being rather improbable. There is a broad peak between 20 and 40 Hertz, indicating that these are typical values of for H*L accents. In short, H*L accents have small rise amplitudes but higher fall amplitudes, as expected for falling accents. L*H accents (solid line) show just the opposite behavior: their values are typically between 20 and 60 Hertz, while their values tend to be close to 0, as one would expect for rising accents. The distributions for L*HL accents are given by the dot-dashed lines. They exhibit higher values for both and, reflecting their characterization as rise-fall accents.

Thus, we have shown for the PaIntE parameters (peak alignment), (peak height), (rise amplitude), and (fall amplitude) that their distributions differ depending on which GToBI(S) pitch accent they are associated with, and that the PaIntE model captures the tonal
characteristics of the pitch accents well. As a direct consequence of its
versatility and accuracy, as well as its linguistic underpinnings, the
PaIntE model has recently been employed in a number of intonation
studies, which we detail next.

4 PaIntE in intonation research

In this section, we will present several case studies to illustrate
PaIntE’s potential for intonation research. Moreover, we will
demonstrate that intonation modeling by means of PaIntE can subserve
both the autosegmental-metrical approach (section 4.1) and an
exemplar-theoretic approach to intonation research (section 4.2).

4.1 Autosegmental case studies

We have shown that general rules concerning the phonetic
implementation of intonation categories can be detected in the
distributions of the PaIntE parameters as in the case of peak alignment
in L*H accents discussed in section 3 above. This methodology can
also be employed to test more general hypotheses regarding the
implementation of F0 contours. For instance, Dogil and Schweitzer
(2011) investigated the alignment of F0 peaks in several German and
English databases in this way. Their hypothesis was that there is a
quantal effect in peak alignment that causes speakers to place F0 peaks
either before or after syllable onsets, but not within onsets. This
hypothesis can be motivated by House’s (1996) model of tonal
perception, which claims that tonal contours within onsets are
perceived differently from contours in the nucleus or coda, or by the
observation that syllable onsets are considered ‘weightless’
(Goedemans, 1998).

To investigate if peaks in F0 systematically avoid syllable onsets,
Dogil and Schweitzer (2011) modified the PaIntE anchor norm
normalization method described in section 2.2. Originally, using this
normalization, in each syllable, the unvoiced onset is adjusted linearly
to take up the first 30% of the syllable duration, the voiced onset
and the nucleus to range from 30% to 80%, and the coda to
span the remaining 20% of the syllable duration. In the modified
version, voiced and unvoiced onset consonants were treated the same,
i.e. the onset, regardless of whether it was voiced or unvoiced, was
always mapped to the first 30% of the syllable duration.

Using this modified normalization, Dogil and Schweitzer (2011)
extracted PaIntE parameters from the unit selection database described
above, as well as from a very similar database of a female speaker.
Both databases had been manually prosodically labeled according to GToBI(S). The density plots for all pitch accents in these databases exhibited valleys within syllable onsets in their distributions for the \( b \) parameter (peak alignment), i.e. both speakers avoided placing the peak within onsets. The same procedure was applied to a part of the Switchboard corpus of telephone conversations between non-professional speakers (Godfrey et al., 1992), which was annotated for accent location (Calhoun et al., 2010), and to German audio book recordings from the Librivox project,\(^5\) for which no prosodic annotations were available. The valleys were also present in the onsets when looking at the distributions of just the accented syllables from Switchboard, and when looking at the distributions of all syllables in the audio book corpus, irrespective of whether they were accented or not.

Investigating PalIntE parameter distributions is of course not the only way to carry out intonation research using the PalIntE model. It is also possible to investigate the parameters in a more direct way, for instance by fitting linear mixed models to find which factors affect the PalIntE parameters. For instance, Kelly and Schweitzer (2015) used PalIntE to investigate lexical accents in Trøndersk, a dialect spoken around Trondheim in central Norway. Norwegian distinguishes two lexical accents, named accent 1 and accent 2, respectively. Previous research had found that in Trøndersk the two accents have a similar shape with a high target followed by a low target, but that they differ in the alignment of tones with the segmental string, with a later timing for accent 2 (Kristoffersen, 2006). Also, accent 2 had been shown to have a higher \( F_0 \) minimum than accent 1 (Kelly and Smiljanić, 2014).

Using PalIntE, Kelly and Schweitzer (2015) could confirm the previous findings on the later timing of the peak in accent 2: they found that a linear mixed model predicting syllable-normalized parameter \( b \) (peak alignment) with accent type as a fixed effect was significantly better than the corresponding model without accent type, i.e. peak alignment depends on accent type. The study also provided new findings, i.e. that accent 2 has a higher \( F_0 \) maximum than accent 1, and that the amplitude of the fall is smaller in accent 2, again by showing that parameters \( d \) (peak height) and (fall amplitude) depend on accent type.

The Kelly and Schweitzer (2015) study is, to our knowledge, the first study using PalIntE to investigate lexical accents. The results

\(^5\) https://librivox.org
demonstrate that the PaIntE parameters can be used to assess aspects of phonetic implementation of lexical accents yielding observations comparable to “classical” implementation studies that measure F0 maxima, minima, or turning points. The advantage of the PaIntE model is that these measurements can be derived automatically. This facilitates the investigation of intonation using data on a much larger scale.

4.2 PaIntE in exemplar-theoretic approaches

We have demonstrated in section 3 that the PaIntE parameters are compatible with an autosegmental view of intonation in that they can serve to specify, or investigate, detailed context-dependent phonetic implementations of ToBI-like categories. This is in fact what PaIntE was designed for originally. Here we will show that PaIntE can also subserve an exemplar-theoretic account of intonation. We will briefly introduce the ideas behind examplar theory, and then give examples of research that has used PaIntE to this end.

In recent years, exemplar theory has gained increasing attention, especially in the segmental domain. The key idea in examplar theory as applied to speech (e.g., Lacerda, 1995; Goldinger, 1996, 1997, 1998; Johnson, 1997; Pierrehumbert, 2001, 2003) is that speakers have access to memory traces (“exemplars”) of previously perceived instances of speech in which almost full phonetic detail is retained. Categorizing new instances in speech perception is based on the stored exemplars and their categories (Lacerda, 1995; Johnson, 1997; Pierrehumbert, 2001, 2003); in speech production, production targets are derived from stored exemplars (Pierrehumbert, 2001, 2003).

Under an exemplar-theoretic account phonetic categories are instantiated by accumulations of similar exemplars in memory. It is sometimes claimed that exemplar models negate abstraction in speech production and perception, but this is not the case. The difference to abstractionist models is that exemplar models assume that abstraction arises as a consequence of generalizing over a large set of exemplars (Pierrehumbert, 2003). The aggregation of many exemplars with fine phonetic detail implicitly yields a more abstract linguistic concept with all the properties that the exemplars have in common, leaving all the details in which they vary underspecified. Often it is even explicitly assumed that the exemplars contain category labels (Johnson, 1997; Pierrehumbert, 2001; Walsh et al., 2010; Wade et al., 2010).

Few studies have looked at prosody in an exemplar-theoretic framework. However, it was shown already in one of the first
exemplar-theoretic studies (Goldinger, 1997) that exemplars seem to retain prosodic detail, in addition to segmental phonetic properties: In shadowing experiments, subjects tended to adapt their pitch from their baseline pitch towards the pitch of the stimulus token, and to match the durations of their productions to the stimulus token. The effect was stronger for low-frequency words. This indicates that pitch and duration are stored with the word exemplars, and that these properties are retained in production.

Building on this, Schweitzer (2011) suggested that even more fine-grained prosodic properties, such as peak height, peak alignment, or rise and fall amplitudes, as quantified by the PaIntE parameters, might be stored in memory. In this vein, Calhoun and Schweitzer (2012) proposed that words and short phrases in American English are stored with their intonation contours, and that discourse meanings of highly frequent word–contour pairings can spread by analogy to less frequent pairings. To substantiate this claim, they used PaIntE to parameterize the contours, and calculated duration z-scores for the segments. Representing the contours by attributes derived from these parameters, they identified 15 “typical” contours using clustering techniques. They found that certain words and contours form collocations, i.e., they appeared together more often than would be expected based on their individual frequencies, supporting the hypothesis that words are stored together with their contours. In a perception experiment, they then confirmed that the discourse meanings of the most frequent pairings spread to other word–contour pairings, which constitutes evidence that the contours were indeed lexicalized.

Further evidence for exemplar storage of prosodic properties comes from a series of three experiments (Schweitzer et al., 2015) which demonstrate that phonetic implementation of pitch accents, again in terms of PaIntE parameters, is subject to frequency of occurrence of the linguistic context. We will only address the first of these three experiments in more detail here, as it investigates accent implementation in terms of PaIntE parameters directly and thus can serve to illustrate how the PaIntE parameters could be interpreted as dimensions in storing intonation contours. The other two experiments also utilize the PaIntE parameters, however they are used to assess frequency effects on the similarity or dissimilarity of accent shapes.

The experiment described by Schweitzer et al. (2015) uses a database which was manually annotated for GToBI(S) pitch accents (Mayer, 1995). Using generalized linear mixed models, the authors show that accent range in L*H and H*L accents, as quantified by PaIntE parameters and , respectively, is significantly affected by the
frequency with which the accent and the specific word cooccur. Traditional autosegmental models of intonation, which assume that intonation is post-lexical, cannot easily account for such frequency effects, while exemplar models offer a parsimonious account: It is assumed that in production, a number of exemplars that match the required target best are activated, and that speakers average over these exemplars, or randomly sample from them, to arrive at a concrete production target. Thus if a pitch-accented word is to be produced, and if sufficient pitch-accented instances of this word are stored in the speaker’s memory, the derived target will match those exemplars and is thus expected to exhibit an F0 amplitude that is appropriate for pitch-accented words. If on the other hand only few pitch-accented exemplars of this word are stored, other, non-accented exemplars will contribute in deriving the production target, leading to a reduced F0 amplitude.

In summary, we would like to argue here that in an exemplar-theoretic account of intonation, the detailed intonational properties that are assumed to be stored with each exemplar can be captured by the PaIntE parameters. We do not necessarily advocate an exemplar-theoretic approach to intonation, but we would like to note that given the problems with labeler consistency and human labeling time which will be discussed in the following section, an exemplar account does have a certain appeal. However, it should be noted that at least in the second study discussed here (Schweitzer et al., 2015) it is still assumed that exemplars might be labeled with concrete intonation category labels, i.e. it does not make such categories obsolete.

5 Discussion

In this section we will discuss several theoretical and practical problems of intonation modeling arising from the assumption that the intonation structure of utterances can be described in terms of a linear sequence of intonation events that represent intonational categories. We will then move on to discuss the characteristics of PaIntE that allow for a mapping of F0 contours to established intonational categories, but also for analyzing and generating F0 contours in a scenario in which one prefers to remain agnostic with respect to the validity of such categories.

Autosegmental models of intonation aim at establishing a set of intonation categories which, analogously to phonemes in the segmental domain, serve to distinguish meaning. This idea has driven most intonation research in the past 50 years or so (e.g., Goldsmith, 1976;
Bruce, 1977; Gussenhoven, 1984; Ladd, 1996), with the Tone Sequence Model (TSM, Pierrehumbert, 1980) and its extension to the ToBI labeling system for American English (Beckman and Ayers-Elam, 1997) as one of its most prominent and probably most widely accepted approaches. However the categories proposed by these models are far from being as established as their segmental counterparts: Even models that do agree on the autosegmental approach differ in the specific inventory of categories that they suggest. In the case of American English, Dilley and Brown (2005), for instance, propose a set of categories for American English that differs from that of the TSM, or ToBI. Similarly, for German a number of models have been proposed in the autosegmental tradition, all of which assume different category inventories (Kohler, 1991; Féry, 1993; Mayer, 1995; Grice et al., 2005; Peters, 2014). The ToDI transcription system for Dutch intonation (Gussenhoven, 2005) focuses on the transcription of tones and limits the number of boundary categories to two, viz. utterance and intonation phrase boundaries, without accounting for different strengths of boundaries (unlike ToBI).

Setting aside the problem of agreeing on one authoritative set of categories, a further problem is that even if the categories are taken as given, it is not easy to unambiguously identify these categories in speech data, as evidenced by the moderate consistency with which human labelers can identify them. For instance, regarding labeler consistency for ToBI pitch accents in spontaneous data from the Switchboard corpus (Godfrey et al., 1992), Yoon et al. (2004) report a Kappa coefficient of $\kappa \approx 0.51$ for inter-annotator agreement on the type and presence of pitch accents. However, these moderate consistencies are achieved only when collapsing ToBI pitch accents into two broad categories H* and L* plus a class X* for uncertain cases; the consistency for the original ToBI inventory must be expected to be even lower. Another study (Syrdal and McGory, 2000) on read speech using the original ToBI inventory reports more promising values of $\kappa \approx 0.67$ for ToBI pitch accents in a male corpus, and of $\kappa \approx 0.69$ in a female corpus, indicating substantial, but far from perfect agreement. These corpora, however, consist of read speech by professional newscasters, which has been claimed to be easier to annotate than more spontaneous speech (Mayo et al., 1997, p. 234), and they were annotated by trained and experienced transcribers only.

---

Note that research papers cited in this section are not always explicit about which version of Kappa (e.g., Cohen’s Kappa, Fleiss’ Kappa, etc.) they have used.

Perfect agreement is said to occur when $\kappa \geq 0.81$ (Landis and Koch, 1977).
While newer studies report the $\kappa$ coefficient to quantify between-labeler consistency, the first systematic evaluation for ToBI assesses consistency in terms of percentage of matching transcriber/word pairs (Pitrelli et al., 1994). To calculate the percentage of matching transcriber/word pairs, they carried out pair-wise comparisons for each word and each transcriber, accumulating the number of cases where any two transcribers agreed on a particular label (or non-label) for a word, and finally dividing this number by the total number of pairs where transcribers either agreed or disagreed. Using this measure, they reported 68.3% consistency for pitch accents, while Syrdal and McGory (2000) report 71% for their female corpus and 72% for their male corpus. Similar values of 71% were reported for GToBI pitch accents in German speech data (Grice et al., 1996) and slightly lower values for GlaToBI pitch accents in spontaneous Glaswegian English with 62% for non-expert labelers, and 69% for expert labelers (Mayo et al., 1997). Yoon et al. (2004) report a higher percentage of 86.57%, but this again refers to the consistency in labeling their reduced set of pitch accents. Insufficient transcriber reliability was the motivation for the development of ToBI Lite (Syrdal et al., 2000), reducing the set of pitch accent categories in American English to two (rising vs. falling), which also served as the basis for the automatic recognition of these categories with high accuracy (the actual inter-transcriber consistency was not reported).

Both $\kappa$ coefficients and transcriber/word pair accuracies suggest that intonation categories are more elusive than the categories in the segmental domain, where $\kappa$ values above 90% are not unusual (e.g., Gut and Bayerl, 2004). In addition, to make use of these categories in intonation research, sufficiently large databases need to be available which are annotated accordingly. However, manual annotation of these categories is extremely time-consuming. Syrdal et al. (2001), for instance, found that experienced labelers take 100 to 200 times real time for annotating ToBI labels.

The fact that human labeling of intonation categories is both time-consuming and prone to labeler inconsistencies makes automatic labeling of these categories all the more attractive. One of the most interesting aspects of the PaIntE model is that it can actually be used to tackle this issue: Schweitzer and Möbius (2009) used the PaIntE parameters to predict pitch accents and boundary tones. They obtained accuracies of approx. 78% in the annotation of pitch accent types, and accuracies of approx. 86% when addressing the annotation as a two-class problem, i.e. when predicting presence vs. absence of pitch accent rather than type of pitch accent. These results are slightly but probably
not significantly better than those reported for read data by other recent studies\(^8\) (e.g., Hasegawa-Johnson et al., 2005; Sridhar et al., 2008; Rosenberg, 2009).

Unfortunately it is not valid to directly compare the accuracies reported above to human labeler consistencies in terms of percentage of correct transcriber/word pairs, and studies on automatic labeling do not usually provide \(\kappa\) values. However to give an impression of the expected values, we used the WEKA toolkit (Witten and Frank, 2005) to calculate \(\kappa\) values for the results reported in Schweitzer and Möbius (2009), obtaining \(\kappa \approx 0.62\) for presence/absence and type of pitch accent. This indicates that there was a better consistency between the automatically predicted labels and the human gold standard labels than between human labelers in the study by Yoon et al. (2004), who reported \(\kappa \approx 0.51\), but a lower consistency than that reported by Syrdal and McGory (2000) for experts’ labels, which was \(\kappa \approx 0.67\) and \(\kappa \approx 0.69\) in a male and a female corpus, respectively.\(^9\)

To conclude this section, we have argued here that the categories assumed by phonological models of intonation are more elusive than the categories in the segmental domain. Thus, two advantages of the PaIntE model are, first, that it does not depend on the assumption of such categories. Instead, the PaIntE parameters allow for quantifying established parameters such as peak height, peak alignment, or rise and fall amplitudes, on a continuous scale. This can also be exploited under an exemplar-theoretic account of intonation, as discussed in section 4.2. Second, if a phonological perspective is preferred, the PaIntE model can be used to automatically label intonation events with an accuracy close to that of human labelers.

6 Conclusion

The PaIntE model can be used, in an analysis mode, to approximate the shapes of natural F0 curves and, in a synthesis mode, to generate F0 contours that sound convincingly like natural ones. The model considers the intonation structure of an utterance as consisting of a

---

\(^8\) Comparing these results is straightforward because the data are similar: they all report results for the two-class problem, deriving the accent status from ToBI labels. All corpora consist of news-style read speech by professional speakers. However, it should be noted that the corpora are from two different languages with different ToBI systems.

\(^9\) We have only reported consistencies for pitch accents here; it should be noted that consistency for boundary tones is usually higher than for pitch accents, indicating that the boundary categories are easier to identify than pitch accents and in that respect are less problematic in our view.
sequence of intonation events, which can be mapped to elements of the linguistic structure, with simple contour interpolations between these events.

By default, PaIntE considers ToBI categories as relevant intonation events. This is an obvious choice, given the prevalence of the autosegmental model in intonation research. ToBI categories are, at least, a good approximation of salient intonational events. Mapping PaIntE parameter values to these categories therefore facilitates the comparison of results across otherwise different approaches in phonological and phonetic intonation research. Moreover, evidence of a correlation between ToBI-like categories and the PaIntE parameters was found by Möhler (2001) who reported that the acoustic distance between natural and generated F0 contours is smaller when GToBI(S) categories are taken into account than when parameter values based on generic clustering were used. However, if no annotation of intonation events is available, PaIntE parameters can be extracted for each syllable in a given utterance. This approach was taken, for instance, in first-language acquisition studies with young children whose productions cannot be described adequately by means of adult ToBI-like categories (Lintfert and Möbius, 2012).

In this chapter we have presented the motivation behind the PaIntE modeling approach and its mathematical formulation. The PaIntE function comprises a small number of parameters with a linguistic interpretation whose values are estimated, learned, and generalized from speech databases. We explained the procedure of extracting the parameters from observed F0 contours and how to predict them, for instance, in the context of speech synthesis. Furthermore, we discussed the relation between the PaIntE intonation events and intonational categories posited by autosegmental approaches to intonation modeling. Finally, we presented several recent studies employing the PaIntE model. They show that PaIntE is a valuable contribution to intonation research beyond speech synthesis, which can serve to answer research questions both in the autosegmental tradition and in an exemplar-theoretic framework.
