Introduction to Linux for IMS students

This script is intended as an introduction to Linux and Linux shell commands in the IMS computer pool for students. I prepared this for the Methods in Computational Linguistics class in winter terms 2016-2021.

Why will you need Linux shell commands at IMS? Because many classes at IMS will require you to have some knowledge of them - sometimes basic knowledge, sometimes more advanced knowledge. Classes where you will be using these commands include Text Technology, Syntax, Information Retrieval and Text Mining, the Computational Linguistics Team Labs, Speech Synthesis, Speech signal processing, just to name a few. It's also very likely that you'll need this for practical experiments with IMS tools during your thesis project.

This script is intended as a tutorial for self-studying, and I will offer hybrid sessions where we can deal on an individual basis with whatever problems occur, address things that may not be explained clear enough in this tutorial, or where I can help you if you got stuck.

You don't need to have started working through this script before the first session, but I would advise you to do so. We will have only three sessions to get you through this tutorial, and keeping the pace will cost different amounts of self-study time depending on your previous knowledge. There will be two sessions in the first week, to get you started, then a break in which Sabine Schulte im Walde takes over for some introductory sessions, then I will teach the speech part of the Methods class. After that, there will be a third, concluding session where you can ask any remaining questions about the Linux part. This will be roughly after 4 weeks, and it will be the last session taught by me, before my colleagues take over. This is to give those of you who are very new to Linux enough time for self-studying before the final Linux session. Please try to put in much self-study time right now if you don't have much computer experience, because even though you could continue to work your way through this tutorial on your own later in the year, it's much easier to do it while you can ask me in the sessions.

I hope you have fun doing this – I was intrigued when I learned what you can do using Linux commands, so I hope you'll find them helpful, too. I am also grateful for any feedback on this tutorial – if you feel that something is missing, or would like more examples, please contact me at

antje.schweitzer@ims.uni-stuttgart.de

Thanks! 10/18/21
Terminal and Shell

Before we start, here's a piece of advice: Instead of viewing this document in your browser, download it to your computer (right-click and save) and view it with a PDF viewer that shows the list of contents as clickable bookmarks next to the document itself. I've structured this tutorial into several chapters and I've tried to make the names telling enough. This way you can navigate through the document more easily.

A terminal used to be a device to get data into and from a computer. Originally, these were hardware devices which were hooked up to a "big" computer, and they looked like typewriters with a black screen. Nowadays, we still use terminals as one way of interacting with our computer; however, these terminals are just software applications which behave like a terminal: they are terminal emulators. But their icons are still reminiscent of the old terminal devices, they may look like this:

So how can you get a terminal? This depends on your operating system.

- **Under Linux**, you'll probably find it in your dock, ready to be launched. If not, look for it in your Applications menu. You may also be able to search for Applications. Just search for an application called "Terminal", then launch it.

- **Under Mac OS X**, it's also easy: either look for it in a subfolder "Utilities" inside the Applications folder; or use the Spotlight Search (press <cmd> and <space> keys together), then start typing "Terminal".

- **Under Windows**, there usually is no Terminal. But on older Windows systems, you can install PuTTY. This is a Terminal emulator for remote connections under Windows. Once it is installed, you find it in the Start Menu; alternatively, you can type "PuTTY" in the search field right next to the Start menu. When you run it, a dialog box for configuring PuTTY pops up; we'll see what to enter in this box in the next section below.

- **Recent Windows** systems come with the PowerShell as a Terminal emulator; in this case you won't urgently need PuTTY. However PuTTY is

---

1 If you are not using your own computer, but are sitting in the computer pool, please skip to subsection "The window manager and the terminal on IMS computers" below.
still recommended for running applications that use a GUI (you'll learn about this later in this tutorial). If you don't want to install PuTTY, you can start the PowerShell by typing "PowerShell" in the search field next to the Start menu. If you did install PuTTY, type "PuTTY" in the search field.

Now that you've started a terminal, you can use it to interact with your operating system. However, the exact commands differ from operating system to operating system. Here we will look at how to interact with the Linux system at IMS. To this end, we'll first need to connect to IMS in your Terminal.2

**Connecting to IMS**

We will use the ssh protocol to connect to the IMS servers.

- If you are using a **Linux or Mac OS X terminal, or the PowerShell** (with PuTTY: see below), you simply type the following into the terminal window:

  
  ssh USERNAME@phoenix.ims.uni-stuttgart.de

  and hit the <ENTER> key. Please replace "USERNAME" in the command above by the user name you have been assigned for your IMS account. It should be 8 lower case letters; typically the first 6 letters of your last name followed by the first and last letter of your first name. If you don't have one, please look at the link "Getting an IMS user account" in the Welcome session of the Methods class on ILIAS, or in the Linux folder (also in the Materials for Methods on ILIAS).

  You will be prompted for your password then. Possibly you'll see a message like this

  The authenticity of host 'phoenix.ims.uni-stuttgart.de (141.58.127.109)' can't be established.

  ECDSA key fingerprint is

  SHA256:9HVMPTXnbAWiFhb3f4Hu5L8YFov7JqHuHwUo0GZx2o.

  Are you sure you want to continue connecting (yes/no)?

  whis is ok. Once you've confirmed, you'll probably see:

  Warning: Permanently added 'phoenix.ims.uni-stuttgart.de,141.58.127.109' (ECDSA) to the list of known hosts.

  And then next time, your computer will remember this server and won't ask again.

2 But keep in mind that you could also use the Terminal for interacting with your local computer - especially if you have a Linux system or a Mac OS - in this case, most commands introduced in this tutorial should work; however the organization of files in your file system will differ.
• If you are using **PuTTY**, you need to enter the server details into the dialog box for configuring PuTTY:

Click on category "Session", and enter

phoenix.ims.uni-stuttgart.de

as Host name. The port for ssh (22) should already be specified. If you want, give this configuration a name by typing a name into "Saved Sessions", then press "Save". Then, start the session by hitting the "Open" button. Next time, you can load that session before opening the connection.

When you connect for the first time, you will see a box warning you that the authenticity of the server cannot be established ("The server's host key is not cached in the registry..."). Hit "Yes" anyway. You will then be prompted for your user name "Login as:". Type the username of your IMS account now (see explanation in the Linux section above for more info on your username). Finally, you will be asked for your password.

A short note regarding the server: I've suggested to use phoenix. This is a server intended for students which has 40 CPUs. However even then it can get "crowed" sometimes (this means it will be slow because many students are running processes on it at the same time). In this case, you can also try to use one of the computers that you would normally use in the computer pools. Here are some of their names: bergente, brillenente, dunkelente, eiderente.

No matter which Terminal emulator you were using, or exactly which IMS server you were connecting to, you should now see a line that looks like this:

[USERNAME@phoenix ~]$  

where instead of USERNAME you see your username, and instead of phoenix you may see a different server name. This is the so-called prompt, and it indicates that the **shell** is ready to take commands from you. Before we go on to work with the shell, here's how you get a shell if you are actually sitting in the IMS computer pool, at one of the student desktops there. If you are currently using your own computer, you can just skip that next subsection for now, but you may find it useful later during the semester in case you want to use the computer pool.

**The window manager and the terminal on IMS computers**

If you log into a computer in the IMS student pool using not a remote shell, as described above, but by physically sitting at that computer, using it as the local host, here's what happens:

After logging in, the so-called window manager decides what your desktop
looks like, which windows are opened, etc. The default window manager at IMS is Gnome, and this tutorial will assume that you are indeed using Gnome. You can select other window managers (or switch back to Gnome, in case you have changed it) after you have entered your user name: click on the little gear wheel next to the "Anmelden" ("Login") button, and select Gnome.

Once you see the desktop, hit the "Windows" key:

![Windows key]

This will give you a dock for your "favorite" programs on the left of the screen, and a field for searching programs and settings at the top of the screen. If you start typing something now (no need to click into the field!), the characters will automatically appear in the search field, and Gnome will display a choice of programs that match your search.

You can start the programs that appear by left-clicking on them. You can also drag them to the dock of favorite programs permanently. To remove them from the dock, hit the Windows key to get the dock, then right-click on the program, select "Entfernen" ("Remove").

Let's make use of the search field a first time: If you want to **change the language of your desktop and all the menus**, you can do so by starting the Settings application: use the Windows button as described above to get the search field, then start to type "Einstellungen", which is German for "Settings". The icon of that application shows a gear wheel. Click on it, then select the Flag to change the language and region settings. You can then change the language by clicking on the first line "Sprache Deutsch" (which means "Language German"). A list of languages will come up; I strongly recommend selecting English over your native language (because it's easier to get help on English error messages, both from lecturers at IMS and from the internet)\(^3\).

Once you've selected the language, Gnome will require to be restarted in order for the changes to take effect: there will be a small blue button "Neustart" ("Restart") that you should click. It'll tell you that you will be logged out, which you have to confirm. Log back on after that. When you do so, Gnome will ask you if you want to change the names of some folders that Gnome always creates for users: folders such as the Desktop, a folder for Documents, etc. So these had been created with German names for you ("Schreibtisch" for "Desktop" for instance), and Gnome is now asking whether you want the English names instead. Make your choice, and then we can continue with our first Linux commands.

\(^3\) If you don't like to use the search field for getting to the settings dialog, you can alternatively click on the "Power" button in the top right corner of your screen. This brings up a small dialog box, and in its bottom left corner there is that little gear wheel which opens the settings dialog.
Hit the Windows button again to see the dock. It should usually contain the most important programs/applications – Firefox as a browser for the internet, Thunderbird as a mail client, etc. It should also contain an application called "Terminal". Its icon looks like a small black monitor:

If not, search for the Terminal application and drag it into your dock, then start it. You should now see a line that looks like this:

```
[USERNAME@phoenix ~]$  
```

where instead of USERNAME you see your username, and instead of phoenix you will see a different computer name (in the pool, all computers are called something ending on -ente (which is German for "duck").

This is the so-called prompt, and it indicates that the **shell** is ready to take commands from you.

### The shell

The shell is the program you use to interact with your operating system – in this case, Linux. If you log into an IMS server as described above, there will be a Linux shell running in the Terminal. You can interact with the system through this shell.

If the shell is ready to interact with you, it displays a **shell prompt** at the beginning of the line. This prompt often ends with a ">" sign (this is alluded to in the icon for the Terminal, see above!), or a "$" sign. Sometimes more info is displayed at the prompt, but we'll get to this later.

There are lots of single commands that you can use for interacting with the operating system – for instance, commands for listing files in a folder, for navigating through the hierarchy of folders on your computer, for displaying info on files, for manipulating and viewing files. You can even start all applications and programs by single commands in the shell instead of clicking on the icon.

It is also possible to write a sequence of commands into a file and then have the shell execute all commands in that file. This is called a **shell script** – a sequence of single shell commands to be executed in one go. They are very helpful for automatizing typical sequences of commands.

There are different shells with slightly different syntax, the most wide-spread are probably tcsh (pronounce t-c-shell), csh (c-shell), bash (pronounce bash, or Bourne shell). Since the bash is the default shell for all IMS users, we will
assume bash in this tutorial.

You can check the shell type by checking an environment variable called SHELL. This variable should hold the shell program itself. If you want to refer to the content of variables in the shell, you need to prepend a $ sign to the variable's name. Thus we can use a command called echo and type

```
> echo $SHELL
```

to get the content of the SHELL variable displayed. Please don't type the ">" symbol, throughout this tutorial it is just supposed to indicate that the above constitutes a command that is to be typed after the shell prompt. The above command should (usually...) display the user's preferred shell program itself, in our case hopefully:

```
/bin/bash
```

For the rest of this tutorial, we will use the following conventions: commands that you are supposed to type at the prompt are indicated by the ">" sign for the prompt, and set in the TT font used in the > echo $SHELL example above. I will display the shell prompt in front of the command to emphasize that this command should be typed at the prompt. The prompt itself should of course not be typed in. For displaying output of the shell, as the /bin/bash above, I'll use the same font, but no prompt symbol.

The echo command above is actually the very first shell command that we have used. In the above example, we have used the echo command with $SHELL as an argument. The $ sign directly in front of a symbol name indicates that we are dealing with a variable. The echo command simply prints whatever you give as an argument – however it replaces variables such as $SHELL by their content. So the above example worked because the $SHELL variable was set to /bin/bash, and this is what echo displayed.

If we were more playful, we might type

```
> echo I love using a $SHELL shell
```

and this would simply repeat the sequence of arguments, replacing the variable by its content, but leaving the rest unchanged. Try it out.

**Configuring the shell prompt**

It is possible to configure the shell prompt to display various information. What information is displayed is determined by an environment variable called PS1. Use the echo command above to display its content:

```
> echo $PS1
```

Don't forget the $ in front of the PS1 in the above command! If you run the
command correctly, at IMS, you'll probably see a string such as

```
[\u@\h \W]\$
```

where the letters with slashes indicate variables. There are many options for what variables to use in a prompt, here's a list of the most popular ones:

- \w  the directory (folder) that you are in
- \W  only the last part of the directory that you are in
- \h  the host name, i.e. the name of the computer
- \u  your user name
- \s  the name of the shell

So in the above example, each prompt will indicate in square brackets the name of the user (\u), then an @ sign, then the name of the computer (\h), a space, and the directory (i.e. the folder) you are in (\W), and the prompt will be terminated by a "$" symbol after the closing square bracket. This could look like this (note that ~ is an abbreviation for your home directory, we'll learn this later):

```
[schweitt@bergente ~]$ 
```

or like this if you were in a folder called Dokumente below your home:

```
[schweitt@bergente Dokumente]$ 
```

To avoid confusion (because variables are also indicated by the $ sign), I recommend changing the prompt so it does end on ">", as I assume in this tutorial. To do this, we need a command to assign a variable a new value. For setting environment variables like PS1 in bash, we use the command `export`, for instance as in this command which configures my favourite custom prompt:

```
> export PS1="\u@\h \w> " 
```

As you can see, `export` takes the name of the variable (without the $ this time, because we don't mean the variable's content but the variable itself!) and then an equal sign and then the value that the variable should be set to – in this case, the string that we want for the prompt. The @ symbol above doesn't mean anything – it's just a nice way of stating that this is me working at "@" my computer, so it could look like this:

```
schweitt@bergente ~/Dokumente>
```

Changing the PS1 environment variable in this way will only affect your current bash. So you'll have to reset the prompt in every new bash shell for now. However, we'll learn later how to change it permanently.
Directories and files

Case matters

Beware – in Linux and Unix, case matters!!! This means that `file.wav` and `File.wav` and `FILE.WAV` are all different files and may even co-exist in the same directory.

The directory hierarchy

In Linux, all directories (or "folders") are organized in one directory tree. The top node is called the root node. The symbol for the root node is `/.

```
bin  dev  etc  home  mount  tmp  usr  ...
...  ...  ...  users0  ...  users21

anna  flo  jenny  ...

lectures  exercises  papers  ...
```

This is what the directory tree on a Linux machine could look like. Please note that this is an example, and that users anna, flo and jenny don't actually exist at IMS.

Anyway, every directory can then be addressed by its path along the directory tree, joining directory names by more "/" symbols. Here is an example: In the above hierarchy, you would address user anna's exercises directory as

```
/home/users0/anna/exercises
```

This means it can be reached by starting from the root node (the first "/" in the path above), continuing into a directory called "home" into one called "users0" into directory "anna" into directory "exercises".
The working directory

It is important to understand that when you are running a bash shell (or any shell, for that matter), you are always inside some specific directory, which is called the working directory. Your working directory will always be some directory inside that tree.

The tree above is similar to the one at IMS, but I've made up the directories for anna, jenny, and flo, and left out a few others. So of course the tree is not exactly correct and also not complete, and it will certainly look a bit different on different machines and different Linux systems. But in any case, each user has one so-called home directory in which all their personal files can be written. And it is very common for Linux systems to have the home directories somewhere below /home (i.e. below a directory called "home" which is directly beneath the root node – note that /home obviously must refer to a directory directly beneath the root node because its path starts with "/").

When you log onto the IMS servers, you will always get a shell in which you currently are in your own home directory, i.e. when you start, the working directory is your home directory. You can check the working directory with the following command:

```
> pwd
```

pwd is short for "print working directory". You can of course change the working directory in the course of a session. Since it's easy to forget in which directory you currently are, you might need the command above frequently during a session. Alternatively, if you have configured your shell prompt to display your working directory, that may save you the effort of checking the working directory all the time.

Navigating and listing the directories

The command to change the working directory is

```
> cd <DIRECTORY>
```

where cd is short for change directory, and <DIRECTORY> is the argument to the cd command. In the above notation, the <DIRECTORY> is supposed to be just a placeholder, or a "template", for an argument, with the <> brackets indicating that this is a placeholder, which you should replace by something sensible (without the brackets then!!). I will continue to use this kind of notation when explaining the general use of commands. The placeholders will always be in upper case with these brackets, and I will try to use names that indicate what the intended arguments are – in this case here, they are directories.

So far, we have learned that you can refer to directories by their paths along
the directory tree, starting from the root node. So in our example, we could change to the lectures directory beneath user anna's home directory by

```bash
> cd /home/users0/anna/lectures
```

or we could do this in many steps and first change to the root directory by

```bash
> cd /
```

followed by

```bash
> cd home
> cd users0
> cd anna
> cd lectures
```

Please note that if you don't specify an argument as in

```bash
> cd
```

you will end up back in your own home directory.

There's no fun in navigating the directories if you can't at least peek into them, so the next command we learn is

```bash
> ls
```

which is short for "list". In the above form it simply lists the contents of the working directory. Alternatively, specify a directory as an argument

```bash
> ls <DIRECTORY>
```

as in the following examples

```bash
> ls /home/users7/schweitt/lectures
> ls /home/users7/schweitt
> ls /
```

ls can even take more than one argument, so you might want to list several directories in one go as in

```bash
> ls <DIRECTORY1> <DIRECTORY2> ... <DIRECTORYN>
```

Also, ls does not only work for directory arguments, you can also use it to list one or several files, i.e.

```bash
> ls <FILE>
> ls <FILE1> <FILE2> ... <FILENAME>
```

which does not give us a lot of information except that it does not work if the files don't exist – in this case, there will be an error; if the files exists, you'll get their names repeated back to you. However, we'll get to a bit more advanced uses of the ls command later, and then it will make sense for both
directories and for files. Before that, we'll have a look at another way to refer to specific directories and files.

**Relative and absolute paths**

So far, we have referred to directories by specifying the full path from the root node to the directory. In the same way, we can refer to files by specifying the full path, for instance

> ls /home/users7/schweitt/lectures/document1.pdf

The full path from the top node down to the directory is called the **absolute path**. However, it is almost always more convenient to give a **relative path**, and relative means: relative to the working directory.

So relative paths only make sense in combination with some working directory, some "current position" in the directory tree. For instance, if you have changed to user schweitt's home directory

> cd /home/users7/schweitt/

and inside that home there is a folder called "lectures", as assumed above, you can list the contents of this folder by

> ls lectures

This is a relative path, and the shell will figure out that it has to prepend the path to your working directory to this relative name in order to get the absolute reference, e.g. /home/users7/schweitt/lectures. You can tell that it's a **relative path because there is no "/" symbol in front of the name**.

Depending on where you currently are in the directory tree, the above file might be referred to in a relative way as

> ls lectures/document1.pdf
> ls schweitt/lectures/document1.pdf

So now we know how to refer to files or directories that are somewhere beneath the working directory by using relative paths. The only thing missing is: how to refer to files or directories that are higher up in the tree. For this, we use "..". This means "one directory up", and you've seen it many times when you navigated the directory trees using a graphical interface, both under Windows and under Linux: to get one directory up, you have to click on "..".

So if you're in your own home directory, you can refer to schweitt's document above in the following way:

> ls ../../../users7/schweitt/lectures/document1.pdf

And if your home directory happens to be below users7, too, then you're lucky
and can save one level of directories:

```bash
> ls ../schweitt/lectures/document1.pdf
```

Of course relative paths do not only work for the `ls` command, but for any command. For instance, if you are in your home directory, you could change into user schweitt's lectures folder by

```bash
> cd ../../users7/schweitt/lectures
```

or to the top directory by

```bash
> cd ../../..
```

but of course in the latter case, the absolute path would be shorter and more transparent:

```bash
> cd /
```

Finally, there is one convenient shortcut to refer to home directories, and that's by using the "~" symbol. User schweitt's home directory can be abbreviated as in the examples below:

```bash
> ls ~schweitt
> cd ~schweitt
```

If you use the "~" symbol without a specific user name, it refers to your own home directory, i.e. the command

```bash
> cd ~
```

is equivalent to

```bash
> cd ~schweitt
```

**only** if you are user schweitt.

Note that if you want to refer to your current working directory by a relative path, you need to use the "." symbol. So far we didn't need this, but if you wanted to explicitly list your working directory without typing the absolute path, then you could use

```bash
> ls .
```

We didn't need this because if you use `ls` without an argument, it will by default list your working directory as shown above. However, later on you might need it for commands that take directories as argument, because most commands don't make this default assumption.
Creating and deleting directories

Now we know how to navigate the directories, and to display their contents. Before we go on, we'll quickly learn how to create directories, and how to delete them.

The command to create directories is called

`> mkdir <DIRECTORY>`

which is an abbreviation of "make directory".

Try it out: go to your home directory, and create a directory called "MethodsCL":

`> cd`
`> mkdir MethodsCL`

If such a directory exists already, don't worry, nothing will happen, and the shell will notify you that the directory existed already.

To delete it, use

`> rmdir <DIRECTORY>`

short for "remove directory". Again, no need to worry: `rmdir` only removes directories that are empty. So for the directory just created, you should be able to remove it without any problem:

`> rmdir MethodsCL`

Of course, the arguments to `mkdir` and `rmdir` can be specified using relative paths or absolute paths...

**English, please :)**

In case you have tried above to use `mkdir` twice, you have seen a message telling you that you cannot make the directory because it is already there. Unfortunately (at least unfortunate for non-Germans...) this message was probably in German. In order to get English as the system language, you can set yet another environment variable: `LANG`. As you have learned above, you can check what it is currently set to by typing

`> echo $LANG`

which should currently give

```
de_DE.UTF-8
```

so we have German (de) as the language, and Germany (DE) as the country,
and we will use UTF-8 as the character encoding.

Let's set this to English. I strongly recommend using English rather than your native language because it's much easier to find information on English error messages or notifications than on non-English messages. So the setting you might want is `en_US.UTF-8` or `en_GB.UTF-8`... and theoretically you should know how to do that - you have to set the value of the LANG variable to this string, analogously to how you set the PS1 variable above. Want to try it yourself? If not, check the footnote.\(^4\)

Again, this setting will only be remembered for the rest of this session, but we'll see below how we can make it permanent.

**Exercises**

1. Which of these paths are relative paths?
   a) `/home/users3`
   b) `/home/users7/schweitt/lectures/`
   c) `../schweitt/lectures/document1.pdf`
   d) `document1.pdf`
   e) `../document1.pdf`
   f) `~schweitt`

2. Assume the directory hierarchy is as in the example tree above, and you are in user anna's home directory. Give three versions of a command to list the contents of user jenny's home directory (use relative and absolute paths).

3. Let's assume you are in a file system that has a different (unknown) directory structure and you want to change into user max's home directory. What command would you use?

4. How can you query the path to your current working directory?

5. Give a sequence of commands that goes to your home directory, creates a directory called "Exercise" there, and changes into this new directory.
The command line

I am a huge fan of using the command line for almost everything, even if you are actually sitting at the computer you are working on and could easily interact using graphical interfaces. That's because many things can be done in a very efficient way on the command line – especially when using the following tips and tricks.

No mouse pointer, but a history

Conveniently, the shell remembers what you've done in the past. It's very easy to "recycle" commands that you've used before. The easiest is to just use the arrow keys for up and down to go back and forth in your command history. Check it out: the arrow keys display preceding commands at the prompt. If you want to repeat one of those, just hit return, and you are done.

Maybe you want to adapt one of the last commands a bit – no problem, use the arrow keys to get the command back. Then use the left and right arrows in combination with backspace and delete to edit your command. Unfortunately you cannot use the mouse for jumping to specific positions within this command (however you can use the mouse to copy and paste stuff, see below). So you have to navigate inside the command line using the arrow keys, or the <Home>/Pos1 and <End>/Ende buttons. There are also keyboard shortcuts for navigation, and more, in case you want to keep your fingers on the keys – in the following, <ctrl>- means holding the <Ctrl>/Strg button while pressing the second key:

- <ctrl>-a (think "Anfang", or the A in the alphabet) is equivalent to <Home>: go to the beginning of the command line
- <ctrl>-d is equivalent to "Delete" and deletes the character where the cursor is
- <ctrl>-e is equivalent to <End> to go to the end of the command line
- <ctrl>-k deletes/kills anything from the cursor to the end of the line

In addition, you can use the mouse for selecting and copying text. Please be aware that the local operating system determines the copy/paste behavior, you may have to experiment a bit...

Note that it is irrelevant where the mouse pointer currently is, pasted text will always be inserted at the position of your cursor in the command line.

---

5 the exact label on the key depends on your type of keyboard, hope I have covered the two most common versions here
Starting applications from the command line

The shell has its own built-in commands, but in addition, it can execute any program that's executable – the shell just needs to know where the program is located in the file system. There are a number of directories that are by convention used to store executable programs that users might need, and each Linux distribution sees to it that the shell knows which these are (they are kept in another environment variable called PATH; if you are curious, google it – we will not deal with it in this tutorial).

So if you know the name of your application, it's usually sufficient to type its name just like any other shell command, and then the shell will know where to look for it and start it. Here's a few applications that you probably usually start by clicking on their icons, but you may as well type their names in the shell to start them:

> firefox
> thunderbird
> gedit
> evince
> oowriter
> ooimpress

However, all of the above are applications that have a graphical user interface (a GUI), and they open a "new" window on your desktop. You cannot open them if you are logged on remotely as described above. This is because Linux applications that open a GUI rely on a so-called X server running on the machine on which the window should pop up: the X server is responsible for controlling where the window is displayed, and for getting user input from the window. If you are running a Linux system on your local computer, all is well: you already have an X server running. The only thing left to do is to tell ssh that your local X server should be used. To this end, run the ssh command with the option -Y6, i.e.:

```
ssh -Y USERNAME@phoenix.ims.uni-stuttgart.de
```

If you have Max OS X on your local machine, you can install XQuartz as an X Server. Once it is installed, you can run the ssh command with the -Y option as shown above.

If you have a Windows machine, and you are using PuTTY, you can install Xming from [https://sourceforge.net/projects/xming/](https://sourceforge.net/projects/xming/). During installation, you can specify that you don't need an ssh client (you already have PuTTY installed), so enable "Don't install an ssh client"). Once Xming is installed, there is only one modification to make in the configuration of PuTTY: In category "Connection", go to "SSH", open the subcategories (by clicking on the + symbol), select X11. Under X11 forwarding, select "Enable X11 forwarding". Save the configuration. Future connections should then have access to the X server.

---

6 Linux users should use -X instead of -Y as it's more secure. For Mac users -X would probably not work. But if you're concerned about security: google what you have to do as a Mac user to use -X too.
server.

If you have a Windows machine and are using the PowerShell, I don't have a solution - I did not get it to work, and I could not find an easy way around by doing a Google search. However, you can easily switch to PuTTY, and install Xming as described above; then everything should work.

If you don't want to install an X server, that's fine - you do not urgently need it. We will be using it below for setting up forwarding of your IMS mails and for configuring your shell prompt. This can however also be achieved even without opening a graphical window, as I'll explain below.

If you have an X server installed and are ready to open GUI applications - please be warned. These applications run at IMS, and all information about the graphical appearance has to be sent back and forth between your computer and the IMS server: this is going to be slow, even REALLY slow, depending on your connection. So be patient, and use it only if really needed. Opening GUI applications from the shell makes much more sense if you are physically sitting at the computer that the application is running on. But let's assume that this pandemic will be over before you finish your studies at IMS so you can make use of the pool more often. (Sigh.) In this case, you will certainly need to start GUI applications at some point in some practical class in the computer pool.

So what's the benefit of starting applications from the shell? Well, for the first two ones, the Firefox browser and the Thunderbird mail client – none, probably, and especially not if you are logged on remotely. However, for gedit (the standard text editor in Gnome) you can provide the name of the document as an argument, and then the application will start with your document opened already.

We will try this out and create a text document called text.txt. If you have done the above exercise, you should already have created a directory called Exercise. If not, create it now using mkdir. Then change into this new directory using cd.

Now start gedit, giving the name of the new file as an argument. Please put a & sign after the command, as shown below. This tells the shell to run that command "in the background", which means that the shell is not busy and can still interact with you while the command is running (i.e. while the gedit window is open). If you don't put the &, the command still works, but the shell will be busy until you close the gedit window.

> gedit text.txt &

This should open a gedit Window with the new (empty) file opened. (It might take a while, depending on your connection.) Type something, and save. Why is it convenient to give the name of the file as an argument? Well, if gedit already knows which file it is supposed to open and edit, you don't have to go
through a file opening dialog, and also not through a file saving dialog when you're saving the file.

If you don't have an X server running on your local machine, the above won't work. In this case, please use nano as the editor. It's a graphically much more simple editor. In this case, don't send it to the background, i.e. start it without the & sign. But do specify the name of the new file, i.e.

    > nano text.txt

Your terminal will turn into a blank window, with a menu at the bottom. As in the gedit window, you can now type something. You can save using <ctrl>-o (write out) and exit using <ctrl>-x (see the labels at the bottom of the window). If you've set the system language to English before, as explained above, these labels should be English - if not, you'll see German (Speichern for write out, and Beenden for exit.

When you've saved the file, either using gedit or using nano, list the contents of your working directory – hopefully, the text.txt is there... Keep the file, we'll use it later. If all is well, close gedit.

**Hidden files, and changing settings permanently**

Now that we know how to use gedit or nano to create and edit files, we can use it to configure our shell prompt permanently, and to make the language change permanent. In order to do so, we need to look at hidden files first. Hidden files and directories in Linux have names that start with a "." symbol, and the convention is that they are usually not listed. So when we used the ls command above, we did not see them. Similarly, if you use a graphical interface for managing files, such as the Gnome Commander (this application is called "Dateien" in German), they are usually not listed.

If you want to see them, you need to use

    > ls -a

instead of just ls.

Go to your home directory, and try it out.

You should see several entries that start with a ".", and some of them are files, and some are folders – for instance folders in which your settings for your browser or your mail client are stored, or settings for your gnome desktop. The file that we need now is called

    .bashrc

It can be used to add user-specific settings for environment variables etc. for

---

7 If you're an experienced shell user, you can also use vi if you know how to use it.
the bash.

Open it using gedit or nano.

You will see that there is a line

    # User specific environment and startup programs

The # is used for comments in this syntax, i.e. this specific line will be ignored by bash, it's just intended to give users an idea of where to put what.

If you don't have this file, you are probably not in your home directory; in this case, change to your home directory now and try again.

We can now put the definition of the PS1 environment variable that we used above into the .bashrc, below the above comment. This will then set the PS1 variable for all future sessions:

    export PS1="\u@\h \w> "

In the same way we can set the language to English for future sessions by adding

    export LANG=en_US.UTF-8

In case you also want to use English number, date, and time formats etc., you can also set LC_ALL to en_US.UTF-8 - this would automatically include setting the language to English, but also use the other standard English formats. In this case, use instead of the above:

    export LC_ALL=en_US.UTF-8

Save .bashrc and close.

If you want to get the current bash to use this setting starting right now, you can type

    > source .bashrc

Otherwise, it will come into effect next time you start a login shell.

**Forwarding your emails**

This is somewhat unrelated to the shell, but now that we've discussed hidden files, we can quickly configure your IMS email account\(^8\) so all emails get

\(^8\) If you don't know what account I'm talking about: you should have got an info sheet when you applied for your IMS computer account. On that sheet it is explained that with your account you also got an email account (firstname.lastname@ims.uni-stuttgart.de) which you can use. On that sheet it is also explained how to retrieve messages from this account. This is an extra account, in addition to the student account you got when you registered as a student (which would be something like st1234@uni-stuttgart.de). We
directed to your private email account. To do so, change to your home directory, and open *gedit* or *nano* with a file called ".forward".

```
> gedit .forward &
```

Write your private email address into the first line, and make sure you add a line break at the end of the line (i.e. hit the ↵ key on your keyboard). If you want to forward to several addresses, add more lines – one line per address, and the last line needs to have a line break at the end. This year, system administration might already have added your student account here, so decide whether you want to keep the .forward file the way it is, or whether you want to forward to another private address instead. In any case, once you're happy with the addresses you are forwarding to, save the file and close. Make sure that there is no typo.

And don't ever (!) forward the mail from your private account to your IMS account if you are also forwarding your IMS mail to your private account. This creates a really nasty loop that will really, really annoy system adminstration.

**Command-line completion**

Let's return to the command line. Another convenient feature of the command line is that it will try to complete the commands for you if you hit the <Tab> key.

How does it do so? It will assume that the first thing that you type must be some command, since the syntax is always

```
> <COMMAND> <ARGUMENT1> <ARGUMENT2> ... <ARGUMENTN>
```

If you start typing a command and then hit the <Tab> key once, the shell will try to complete that command. If there are several commands or applications that match what you have typed so far, the shell will display all possible matches. If there's only one match left, it will automatically complete the whole command.

For instance, if you start to type "gedit" in a shell on the computers in the IMS computer pool, as soon as you have reached "ged" the only match left is gedit, and at this point, hitting <tab> will complete the name. Before this point, you get the matches displayed whenever you hit <tab> twice – fewer and fewer as you add more characters.

---

*often send talk announcements and job ads or other interesting information to these IMS email accounts, but not to the st-accounts, because no mailing list exists that would reach exactly those student st-accounts that belong to IMS students. So it is recommended to make sure you get these messages. Also, it is easier for IMS teachers to figure out your IMS email address than your student email address, since the st addresses are only accessible to teachers of classes that you are registered for, or examiners of exams you registered for. So if you haven't registered for a class yet, your teacher will not be able to figure out your st address unless you tell them.*
Once you have typed a command or application, the shell knows that
commands and applications often can take one or several files or directories as
arguments, and accordingly, when you type a blank after your command and
then start to type a second string, the shell will try to match this string with a
file or directory. So, to return to the above example with gedit (or nano): Go to
the directory where you have created your text.txt file. Start typing gedit – at
IMS, once you are at "ged", the command should be unambiguous and the
shell completes to gedit. Then if you type a blank and then hit <tab>, the shell
will assume that you will next specify some file in this directory, and if you
really only have the text.txt in your directory and no other file, the shell will
write it out for you even before you have typed its first letter... If you don't
want to give a file in this directory as an argument, but one that's located
elsewhere, start to type the path – no matter whether relative or absolute –
and the shell will try to complete the path. Try and type "ged ." and then hit
<tab> twice – you'll see that the shell will list everything in the directory above
your current directory, and as you specify further letters, will narrow down the
alternatives. Adding a second blank after your first argument will cause the
shell to try to add another file or directory, in the same way as for the first
one. This should work most shells, i.e. also in tcsh or csh for instance.9

**File name expansion and globbing characters**

One last helpful feature of the shell that we will discuss here is that it allows to
refer to files and directories in a more general way by way of name patterns.
This is done by means of so-called **globbing characters**, namely the * and
the ? symbol. * can be used to stand for a sequence of 0 or more characters
(except "/") in a file or directory name, and ? stands for exactly one character
in such a name (again, except "/"). Here's an example:

```
> ls *.txt
```

The shell will extend the string "*.txt" to all files or directories in your working
directory that start with an unknown number of characters, followed by .txt. So
if we had in the working directory three files text1.txt, text2.txt, and
text99.txt, the shell would expand the above command to "ls text1.txt
text2.txt text99.txt" (this expansion is done silently, you don't see it) and so
you get the three file names listed:

```
text1.txt  text2.txt  text99.txt
```

This is one use of *ls on files that actually gives valuable information: we now

---

9 You may have noticed already that bash is even more clever. For instance, it knows that the program
xdiff (a viewer for PDF files) only makes sense with a .pdf file as an argument. So if you type xpdf and a
blank, then hit <Tab>, it will only display files with the appropriate extension, but ignore files with other
extensions such as .txt. If you like, try it out – get a PDF file from somewhere, save it in the same folder
as the test.txt above, then see which filenames the autocompletion offers. This is because bash offers
something called programmable completion. Using this it is possible for each command to specify which
arguments are expected (and even more). For some very common commands, such as xpdf, our Linux
distribution contains such specifications by default. If you want to learn more, google “programmable
completion”.

22
know that there are exactly three files matching the specified pattern. If you want to try this, change to the following directory:

> cd /mount/studenten/MethodsCL/2021/Linux/Globbing

I have created the three files there, so you can test the above command. Please note that you won't be allowed to modify these files, or add new ones in this directory. Don't be shy, this means that you don't need to worry about accidentally deleting or changing anything.

To illustrate the ? globbing symbol, we'll use

> ls text?.txt

In the above case, this would give the following output:

    text1.txt  text2.txt

Here, text99.txt does not match the pattern since there are two characters after the string "text", not only one.

For the sake of simplicity, the examples here assumed that you have changed your working directory to the above directory. However, of course you can use globbing characters in longer paths, so you could also do this from any directory at IMS by

> ls /mount/studenten/MethodsCL/2019/Linux/Globbing/text?.txt

When could this command with globbing be helpful? Often, I hope ;) One scenario: assuming you have several directories for exercises numbered from one to five and want to see for which of them you have files with the extension .pdf, you might need something like

> ls Exercise?/*.pdf

Exercises

1. How can you start a program "in the background"?

2. Specify a pattern that matches all files in /home/users0/anna which have the extension .pdf (i.e. which end on "pdf").

3. Specify a pattern that would match the following file names:
   phonetics1.pdf
   phonetics1.txt
   phonetics21.pdf
   phonetics21.txt

   but not the following file names:
Manipulating files and directories

Copying and moving files

Copying and moving files works similarly in many cases: both can be used in two ways:

`> mv <FILE> <DIRECTORY OR FILE>`
`> cp <FILE> <DIRECTORY OR FILE>`

i.e., they take a file name as a first argument and a "target" directory or a "target" file as a second argument.

If the "target" is the name of an existing directory, then the file is moved/copied to the target directory, keeping its current file name. The only difference between `cp` and `mv` is that `cp` makes a copy and leaves the original file untouched, while `mv` results in really moving the file to the directory.

If on the other hand the "target" is not an existing directory, then it is assumed it specifies a file. In this case the first file will be moved/copied to a file with the specified name – i.e. the new file will have the name specified by the second argument, and the same content as the original file. Please note that if a file of that name existed already, this would result in overwriting the existing file, i.e. the original file will be lost. See below how you can avoid doing this accidentally.

Note that

`> mv <FILE1> <FILE2>`

consequently results in renaming the file to a new name, specified by the second argument. Actually, there is no other "rename" command in the shell; you need to use `mv` for renaming.

Note that moving or copying to a new directory only works if that directory exists – i.e., while both commands may create new files that didn't exist before, they cannot create new directories (how would they even be able to tell whether your second argument was intended to be a directory instead of a new file name?). So to move or copy files to directories that don't exist yet, you need to create these first using the `mkdir` command introduced above.

Both commands can be used with more than two arguments, but only if the last argument specifies a directory:
This will result in copying or moving all N argument files to the target directory.

Remember that the way to refer to your current working directory in a relative way is to use ".". So for instance copying a file called run1.results from the directory above your current working directory to your working directory is achieved by simply typing

```
> cp ../run1.results .
```

The "." symbol works not only for the `cp` command, but for any command.

Since both the `cp` and the `mv` command can cause existing files to be overwritten, at IMS most user accounts are configured to use a more "careful" version of `cp` and `mv`. To understand this, we need to introduce **command options**.

**Command options**

Command options are a way to provide more fine-grained control over a command's behavior or to provide additional functionality. Options are typically specified right after the name of the command and before the arguments to the command. Some options even take their own arguments. Let's look at an example.

The above `mv` and `cp` commands by default don't care if they overwrite existing files. This is dangerous – files that are deleted that way are not stored in some Trash folder, instead, they are really gone forever. The same holds when you remove files using the command for removing, which we will introduce below.

So if you're new to this all, you might want to consider being a bit more cautious and to make these commands ask for confirmation if they would overwrite existing files. Actually, system administrators at IMS sometimes configure new user accounts to use an interactive version of `mv` and `cp`, which always asks. You would usually only get this interactive behavior if you use

```
> cp -i <FILE> <TARGET FILE>
> mv -i <FILE> <TARGET FILE>
```

In the above examples, "-i" is an option that specifies to use the interactive version of `cp` and `mv`.

So on new user accounts at IMS, if you type "cp <FILE> <TARGET FILE>", this might effectively run "cp -i <FILE> <TARGET FILE>", and you will have to confirm or reject the operation by hitting y or n. If you don't like this, there is a way out. Or, if your account is not configured in this way, there's a way to get exactly this behavior.
What the administrators might have done for your account was simply to define so-called aliases. In this case the aliases state that "cp" or "mv" are meant to run "cp -i" and "mv -i" instead. So the "cp" would be a shortcut for typing "cp -i". You can check which aliases are defined for you by typing

```bash
> alias
```

This will list all aliases, with the shortcut or alias, then a = sign, and then the command that is meant to be executed for this alias. You'll see that there are a lot of aliases, and among them, you might find the two for the cp and the mv command. You can also check for specific aliases by giving the alias name as an argument:

```bash
> alias mv
```

If you have an alias defined for mv, this will return the command that is used for mv. So possibly if you do this, you might see

```bash
alias mv="mv -i"
```

If you don't have an alias for mv, nothing will be returned.

It's easy to remove aliases, just type

```bash
> unalias mv
> unalias cp
```

and this will remove the two aliases. Beware, after doing that, you will, for the rest of the session, be using the non-interactive versions of the two commands, which won't care if you're inadvertently overwriting stuff or not. However, you're spared typing y/n for each single file you might want to overwrite.

In case you want to re-define the aliases, or define them in case your account wasn't configured to have them, you can do so by

```bash
> alias mv="mv -i"
> alias cp="cp -i"
```

to get the more cautious versions.

Beware, both alias and unalias only affect the current session; in a new session, you would be back to the original behavior!! So if you want to enable or disable them permanently for your bash, you can again write this to .bashrc. Open .bashrc using gedit or nano, and again put the specification of the aliases below the line

```bash
# User specific aliases and functions
```

Remember that if you want the changes you made to .bashrc to come into
Effect at once, you'll need to type

```bash
> source .bashrc
```

in your home directory after you've changed (and saved) the file. Otherwise they will only come into effect next time you start a shell.

**Copying directories recursively**

Copying empty directories works exactly as copying files. Copying non-empty directories is different: if you try to copy a directory that has files in it, `cp` will notify you that it left out the directory. If you do want to copy the whole thing recursively, you'll need the `-r` option to the copy command, for recursively copying:

```bash
> cp -r <DIRECTORY> <TARGET DIRECTORY>
```

Note that moving directories doesn't need any such option; you can move (or rename) directories like this

```bash
> mv <DIRECTORY> <TARGET DIRECTORY>
```

this will move/rename the whole directory. If `<TARGET DIRECTORY>` exists, `<DIRECTORY>` will be moved inside that directory. If it does not exist, `<DIRECTORY>` will be renamed to the directory location and name you specify, leaving the names of files and other directories inside it unaffected.

**Removing files and directories**

The command to remove files is

```bash
> rm <FILE>
> rm <FILE1> <FILE2> … <FILENAME>
```

For removing empty directories, you can use the `rmdir` command introduced above. If you want to remove non-empty directories recursively, you will again need an option to the `rm` command, in fact, the same as for the `cp` command above:

```bash
> rm -r <DIRECTORY>
> rm -r <DIRECTORY1> <DIRECTORY2> … <DIRECTORYN>
```

Note that this would also work for empty directories, so this is a more general (**but much more dangerous**) alternative to the `rmdir` command.

Again, there is a more cautious version of `rm`: if you specify `rm -i`, `rm` asks before removing files. You can again put an alias for this in your `.bashrc` file, as documented above for `mv` and `cp`. 

27
Permissions and groups

We've learned how to copy, rename and delete files. If you have wondered whether you can manipulate arbitrary files in this way – no, you can't. The file system defines for each file and directory which users can access it in which ways. To see what people are permitted to do for a file, we need the `ls` command again: it provides an option "-l" for "long" listing, and if we use this option, we see much more information than just the file name. If you use it on the file text.txt created in the above exercise, you may see something like

```bash
> ls -l text.txt
-rw-r--r--. 1 schweitt sem1617 13 18. Sep 10:23 text.txt
```

What does this mean? Let's look at the middle part first. The third column states the user name of the owner of the file – in the above case, the user is schweitt. The next column indicates a group of users – here, it's sem1617, which at IMS indicates the group of students who got their accounts in 2016/2017. Groups are useful because they allow to define permissions for a larger group of users which can be different from what everyone else on the file system is allowed to do, and different from what the owner herself/himself is allowed to do.

The next column indicates the size of the file (13 bytes in this case), then we have the date when this file was last changed, the time of change, and the file name.

The interesting part now is the first column. It consists of 10 characters which indicate in this order:

- File type – a regular file (-), a directory (d), or something else which we won't discuss here
- Owner read – owner is allowed read access (r) or not (-)
- Owner write – owner is allowed write access (w) or not (-)
- Owner execute – owner is allowed to execute (x) or not (-)
- Group read – group is allowed read access (r) or not (-)
- Group write – group is allowed write access (w) or not (-)
- Group execute – group is allowed to execute (x) or not (-)
- Others read – others are allowed read access (r) or not (-)
- Others write – others are allowed write access (w) or not (-)
• Others execute – others are allowed to execute (x) or not (-)

So in the above example, we have a regular file; schweitt is allowed to read it (i.e. she can for instance copy the file, or look at its contents) and to write to it (i.e. she can modify or delete the file), but not to execute it (and actually, it wouldn’t make sense to execute a .txt file – executing is for programs). The sem1617 group however is only allowed read access, and so are all other users. The little dot at the end of this first column finally indicates that a so-called SELinux context is defined for that file. We won’t go into detail here, if you’re interested in more, google it. SELinux contexts are a means to control in a more fine-grained way what users and processes are allowed to do with which files, and they help to limit the damage users could do by inadvertently running malware programs.

There’s one column I haven’t mentioned – it’s the one after the permissions. It states how many links there are. However, what counts as a link here is very complicated, and we will not make use of this information throughout the tutorial, so we will just ignore this column here.

If you look at permissions for a directory, these are indicated in the same way. But it’s worth noting that in the case of directories, in order to list their content, permission to execute and to read is required.

Now that we know how to find out the permissions for a file, here is how to change them. The command is `chmod` (for change access mode). It can be used in several ways; here we will only discuss one possible way using what’s called the symbolic notation: after the `chmod` command, one can specify for who we want to change the permissions (u for user, g for group, o for others, a for all three in one go), and then we can add or remove read, write and execute permissions by + and – signs. Here are some examples:

```
> chmod ug+rw text*.txt
```

This would add read and write permissions in all files matching the pattern, for the owner (abbreviated u, the user) and the group (g). It does not change anything in the permissions for others, i.e. these will remain unchanged.

```
> chmod o-rwx Exercises
```

This will make Exercises unreadable and unwritable and unexecutable to others.

It’s possible to recursively change all files below some directory using the -R option:

```
> chmod -R o+rx,o-w <DIRECTORY>
```

would allow all other users to view and execute, but not to modify, all files below `<DIRECTORY>`.
Finally, a user might be in various groups, not only in sem1617, and might want to give another group permissions to some file. To find out the groups that a user belongs to, use

> groups <USERNAME>

For your own groups, it's sufficient to say

> groups

This will list all groups that you are in.

Now if a user is also in group xyz, then they could change the group of the file in the following way

> chgrp xyz text.txt

In general, the command is (either for a single file or directory, or recursively for a directory using option -R)

> chgrp <GROUP> <ONE OR SEVERAL FILES OR DIRECTORIES>
> chgrp -R <GROUP> <ONE OR SEVERAL DIRECTORIES>

But note that these commands are only allowed if the user who runs the command really is in that group. You cannot make a file belong to a specific group that you are not part of.

To conclude this section on permissions, one piece of advice: In my opinion users should give reading permissions as often as possible. It is often very, very helpful to be able to see each other's files, especially when working in groups, or when things don't work and you need help!

**Exercises**

1. Which command do you need to copy the file summary.txt from user schweitt's home to your working directory?

2. How could you copy user schweitt's directory "Exercise" recursively to a folder "Solutions" which exists in your own home directory?

3. What is the command to rename a file called "pirntout.pdf" to "printout.pdf"?

4. Which command would move all files in your working directory which have the extension ".txt" to an existing folder called "tmp"?

5. Which dangerous command would remove all files and directories in your folder ~/tmp (but not the directory tmp itself)? (Be VERY careful if trying this out!!)
6. How can you check the permissions for your own folder ~/Exercise?

7. Which command would you use to take away your own write permissions for file "important.notes.txt" in your working directory? (This would be useful if you want to make sure that it won't be accidentally deleted or overwritten.)

8. Which command would you use to take away your own write permissions for everything beneath the directory "Notes" in your working directory?

9. Assume anna owns the directory which is listed here:

   d-wx--x---. 2 anna sem1617 4096 21. Okt 09:24 Notes.txt

   What is strange about the permissions? Which command would you suggest to give more reasonable permissions?
Inspecting file contents

In many cases, in particular when working on tasks in computational linguistics, the files that you deal with are simple text files which contain only printable characters. This holds for most log files which may be output by some program, it holds for files containing source code, for most label files in phonetics, for most text corpora, etc.

Even though you can of course open such simple text files using a text editor like gedit, or even Microsoft Word, or Open Office Writer, if you just want to take a quick look into such a file it is generally much faster to use shell commands to do so.

One command to achieve this is `cat` (probably abbreviated from "concatenate and print"). It takes one or several files as arguments, and it simply prints everything that's in these files into your terminal – one file after the other:

```
> cat <ONE OR MORE FILES>
```

An interesting option to `cat` is the `-n` option, which will cause the lines in the output to be numbered (however if you supply multiple files, it will not reset the counter to 1 for each new file!).

The `cat` command is often useful; however, if files are long, one can easily get overwhelmed. In this case, the `less` command is helpful because it's true to its name and gives less output than cat: it displays the contents page by page, and it is possible to browse through the pages. It also offers a search function to find specific strings and patterns in the output. It can also take one or several files as arguments.

```
> less <ONE OR MORE FILES>
```

To try it out, we'll need a longer text file. You can find one here:

```
/mount/studenten/MethodsCL/2021/Linux/CasparHauser.txt
```

Copy it to your working directory (as an exercise for repeating the command for copying) and look at it using `less`. While less is running, the following commands are useful.

### Moving around

<table>
<thead>
<tr>
<th>Key</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;space&gt;</td>
<td>page forward</td>
</tr>
<tr>
<td>b</td>
<td>page backward</td>

<td>:p</td>
<td>inspect preceding file (if several files were given)</td>
</tr>
</tbody>
</table>

**Quitting**

<table>
<thead>
<tr>
<th></th>
<th>quit</th>
</tr>
</thead>
<tbody>
<tr>
<td>q</td>
<td></td>
</tr>
</tbody>
</table>

**Character encodings**

Depending on your configuration, you may have observed for the above file that some characters (the German Umlauts for instance) are not displayed properly. There are also some quote symbols that may be shown incorrectly.

If this happens, it's because the above file has its characters encoded in UTF-8 (which allows for a wider range of internationally used special characters by using more bytes for storing single characters). Formerly, in the Western hemisphere, ISO-8859-1 (sometimes called Latin 1) was widespread, and it could also encode Umlauts. It did so in a different way though, and that's why you need to know which encoding is actually used.

You will be able to see the Umlauts correctly only if you have configured both your local terminal emulator and your remote shell to use the correct encoding. In case of CasparHauser.txt, the encoding is UTF-8. If you have set the language of your shell as recommended above:

```bash
export LANG=en_US.UTF-8
```

then you have specified that your shell expects UTF-8. If you still don't see the Umlauts in the file, then possibly your Terminal emulator thinks it's displaying something other than UTF-8. In this case, you will need to find where this can be set. Here's some hints - hopefully you don't need any of them anyway:

- In the Terminal application on Mac OS X, the encoding is hidden in the Preferences dialog: Go to "Profiles" (NOT to "Encodings"). In "Profiles", click on the "Advanced" tab and then select Unicode (UTF-8) under Text Encoding (at the bottom).
- For PuTTY under Windows, the encoding is set in the Category "Window", and there in "Translation". You have to specify the remote character set there. Make sure UTF-8 is selected.
• For the PowerShell, I honestly don't know - my impression is that it is invariably expecting UTF-8 anyway.

• Under Linux, it depends on which Terminal emulator you are using. The settings dialog could be somewhere in the main menu at the top of your desktop, or there could be a settings/properties dialog integrated in the window in which the Terminal appears. You might also get it by right-clicking on your Terminal.

A second problem related to the encoding that you might observe (I have this problem when logging into IMS from a Mac OS X terminal) is that even if you see special characters properly in your Terminal, you might not be able to type them when typing a search string while using less. I don't have a solution for this, but I hope that most of you will not have this problem.
The art of input and output redirection

Standard in, standard error, and standard out

Standard in, standard error, and standard out are "connections" used by programs for reading data, for giving error messages, and for giving back results.

Standard in, or stdin for short, is usually text or information that you type into the shell using your keyboard. Standard error (stderr) and standard out (stdout) are not always easy to distinguish since both connections are typically sent to your Terminal window (but you will see that they behave differently later).

Not all programs use all three "connections"; for instance, the cp command does not get its input from standard in; instead, it always reads directly from a file, and it doesn't write to standard out but to another file. However, in case of errors, it does write that error to standard error (such as "No such file or directory" etc.). The ls command on the other hand does write to standard out: the information on files provided by ls was always simply written into the Terminal window for us. And in case of error messages, it writes to stderr instead of stdout, just like cp. However ls also does not take input from stdin.

An example of a command that can read both from files and from standard in would be the cat command. In the examples of cat we have seen so far, we always specified an input file as an argument. However, if you just invoke the command without any file arguments, as in

> cat

you will see that your shell doesn't display the prompt, as usual; instead it is waiting for input. You can provide input by typing something, then hitting the Enter key (↲) and the <ctrl>-d key combination to terminate the input. You will see that cat simply sends what you have typed to the terminal window (line by line if several lines). Similarly, cat with a file as an argument just sends the contents of the file to the terminal window.

Redirecting standard out

Sometimes it is useful to save the output of a program in a new file. For instance, if we use the -n option to cat to insert line numbers in some file, we might want to keep this numbered version for the future. Or we might want to list all .txt files that we have in our Exercise folder and write the list into a file, so we will remember later which files were present at that point.

To achieve this, we simply use the ">") symbol for re-directing anything that the program writes to standard out into a file. This means the output will not
appear in our Terminal window but will instead be redirected and written into
the file we specify, as in these two examples:

> cat -n /mount/studenten/MethodsCL.2021/Linux/CasparHauser.txt >
CasparHauser.LineNumbers.txt
> ls Exercise/*.txt > List.of.Exercises.txt

Beware, you can easily overwrite files with these commands. By default, the
files that you are redirecting to are either created (if they don't exist yet) or
overwritten. Note however that some accounts might be configured in a way
that the bash will refuse to overwrite existing files. The way to get this
behavior is to set the \texttt{noclobber} variable, which is a built-in variable in bash:

> set -o noclobber

After this, if you try to repeat the above command, which would then overwrite
the CasparHauser.LineNumbers.txt, you get an error, and nothing happens:

> cat -n /mount/studenten/MethodsCL.2021/Linux/CasparHauser.txt >
CasparHauser.LineNumbers.txt
bash: CasparHauser.LineNumbers.txt: cannot overwrite existing file

The command to switch this behavior off (i.e. to allow overwriting existing files
by redirection) is

> set +o noclobber

Yes, this may seem unintuitive, but it wasn't me who invented this...

If you don't want to set or unset \texttt{noclobber} for such cases, it's possible to
specify explicitly that you want your redirection to possibly overwrite existing
files, by appending a "|" sign to your ">") operator. So if you're more cautious,
you might want to set the \texttt{noclobber} so you won't overwrite files, and use these
commands instead of the ones above in cases where you are sure you want to
overwrite:

> cat -n /mount/studenten/MethodsCL.2021/Linux/CasparHauser.txt >|
CasparHauser.LineNumbers.txt
> ls Exercise/*.txt |> List.of.Exercises.txt

The ">|" will overwrite existing files even if \texttt{noclobber} is set.

If you don't like the default behavior that you have in your account, you can
again put the commands to set or unset \texttt{noclobber} in your personal
configuration file, i.e. in \texttt{.bashrc}.

And another word of caution: if you try to redirect into a file that you are using
as input, this will destroy the file. It's easy to try it out:

> echo hallo >| file
> cat file
hallo
> cat file >| file
The sequence above first writes the word "hallo" into a file called "file", and then verifies that this was successful by executing `cat`. As you can see, this outputs "hallo", so the "hallo" was successfully written to the file. It then redirects the output of the `cat` command into the file. The next `cat` shows that the file is now empty.

Instead of overwriting files by redirecting standard out, it's also possible to append standard out to existing files:

```
> echo hallo1 >| file
> echo hallo2 >> file
```

These commands should first create a file, with content "hallo1", then append "hallo2" to that file. Check it out.

**Redirecting stderr**

The commands above did not redirect stderr. You can check this by the following sequence of commands:

```
> echo hallo >| testfile1
> ls testfile1 testfile2 >| output.txt
ls: cannot access 'testfile2': No such file or directory
```

This creates a file called testfile1 (with hallo in it, but that's not central here). Assuming that you do not have a file called testfile2 in your working directory, the following `ls` command should work for testfile1, i.e. it would write its name to standard out. However, for testfile2, you should get an error, and that should go to standard error.

In the example above, you can in fact only see the error, but not the result of the `ls` command on testfile1 (which listed its name) – and that's because that output went to standard out and was successfully written to a file called output.txt. This leaves only the message to standard error to be shown in your terminal. Check output.txt, the name of testfile1 should appear there.

**More on redirection (only for advanced users)**

If you want to redirect stderr, it maybe helps to know that the above operators for redirecting stdout can be more explicitly specified as redirecting everything that goes to "file descriptor 1" (which is stdout).

```
> echo hallo1 1>| output.txt
> echo hallo2 1>> output.txt
```

Now, standard error is equivalent to "file descriptor 2", and accordingly, assuming testfile1 exists, but testfile2 doesn't,
leaves only the filename of testfile1 in your Terminal, and writes the error message to the file output.txt. This can be seen in the second command above: the cat command on output.txt shows the error message of the preceding ls command, which had successfully been written into output.txt. (Instead of overwriting the file called output.txt, we could also append to it using 2>> instead of 2>)}

So in this case the error message went to output.txt, while the name of testfile1 was listed in the terminal. If we want to have both stderr and stdout in one file, and we don't have noclobber set, we can do so by

```bash
> ls testfile1 testfile2 &>> output.txt
```

(Maybe it helps to think that & is an abbreviation for 1&2, so for both file descriptors.) However if we have set noclobber in a way that it refuses to overwrite existing files, we need a more complicated version in case we want to overwrite:

```bash
> ls testfile1 testfile2 >| output.txt 2>&1
```

This tells the shell to add stderr to stdout (2>&1) and to write stdout to the file output.txt (>|) even if the file exists. If you want to avoid this complex notation, use the much easier notation with only "&>", but unset the noclobber variable, or make sure that no file of the name exists before you redirect into it. Sorry it's so complicated, not my fault... But as I said above, this is only intended for advanced users, so if this is overwhelming, just forget about it for now.

**Pipes (for all users)**

One of the coolest features in output redirection is that you can redirect output in a way that it is directly used as the input for the next command. We haven't seen many commands for which this is useful, but there will be many examples in the next section. Here, we'll illustrate pipes using the ls and cat -n commands, cooler stuff will be shown in the next section.

Assume you do not only want to list all files in your working directory, but you might also want to number them. We know that we can list files by ls, and that we can number lines in some input by cat -n. We can now glue the two together and send the output of ls as input to cat (we "pipe" the output of ls into cat). This works because ls writes to stdout and cat can read from stdin, and the | symbol causes the stdout of a command to be used as stdin for the
next command.

> ls | cat -n

We could have achieved the same by first writing the output of `ls` to a file, and then calling `cat -n` on that file, however the above is much quicker, and also saves us the effort of creating and later deleting a temporary file that we do not really need.

It is possible to use pipes even if the second command takes other arguments. So for instance, `cat` can take not only one argument, but arbitrarily many. If you want one of them to be the output from a preceding command, you need to tell `cat` where you want your input to go, so for instance

> echo "Content of list.of.files" > list.of.files
> ls | cat list.of.files -

This would first create a file that has "Content of list.of.files" as its first line. Then `ls` would list all files in that directory, and instead of displaying them in the terminal, the shell would pass them to the `cat` command. The `cat` command first outputs the contents of `list.of.files` (here, only the string "Content of list.of.files"), since that is its first argument, followed by the output of the earlier `ls` command, i.e. the files in that directory – since the position of the "-" in the arguments to `cat` indicates that `cat` should print this last.

**Exercises**

1. Give a command that would list all files in your working directory ending on ".txt" and write the output into a file called list.of.txt.files.

2. Use echo and output redirection to create a file called hello.txt which contains the string Hello.

3. Which command would move the file hello.txt from the previous question into a folder called Exercise, and write potential error messages into a file called move.log in your working directory? Check out if it works by running that command twice. Since the second time around, the file will already have been moved, this should cause an error in the second case, and this error should be written to your move.log.
Useful Linux commands for computational linguists

grep (and regular expressions)

One of the most useful commands IMO is the `grep` command. What it does is that it searches for lines containing certain strings in its input.

So an example of `grep` would be

> grep Apfel CasparHauser.txt

which, given the text example CasparHauser.txt introduced earlier, prints only those lines of the file which contain the string "Apfel". "Apfel", by the way, is German for "apple".

Anyway, you'll hopefully see that there are three occurrences of the word "Apfel", each in a separate line.

Now let's assume as a computational linguist you were interested in the occurrences of the *lemma* Apfel (i.e. the word in any form, singular or plural, and in any case (nominative, dative, etc.) – i.e., interested in any occurrence of either "Apfel" (nom., gen., dat., acc. singular) or "Äpfel" (nom., gen., acc. plural) or "Äpfeln" (dat. plural). This is where regular expressions come into play.

Regular expressions are a way to describe sets of strings. For instance,

```
[AÄ]pfeln\?
```

would describe all strings that start with either "A" or "Ä", then have the letters "pfel", and one or zero occurrences of the letter "n". More generally, the square brackets indicate a range of possible letters, and the question mark with the backslash means: one or zero occurrences of the preceding letter.10

You can put this expression in quotes and give it as an argument to `grep`:

> grep "^[AÄ]pfeln\?" CasparHauser.txt

Here's a list of meta-characters and operators when using `grep`:

<table>
<thead>
<tr>
<th>Description</th>
<th>Example</th>
<th>Strings matching example</th>
</tr>
</thead>
<tbody>
<tr>
<td>^</td>
<td>^Der</td>
<td>Der (at begin of line)</td>
</tr>
<tr>
<td>$</td>
<td>Apfel$</td>
<td>Apfel (at end of line)</td>
</tr>
<tr>
<td>.</td>
<td>.pfei</td>
<td>Apfel, Ipfel, ypfel,</td>
</tr>
</tbody>
</table>

10 Note that you can use egrep instead of grep, which has a slightly different syntax for some operators, and is more powerful. Here, we'll only cover the "normal" grep and basic regular expressions including extensions by the GNU implementation of grep. If you want more, google egrep.
<table>
<thead>
<tr>
<th>except end of line</th>
<th>#pfel, ...</th>
</tr>
</thead>
<tbody>
<tr>
<td>*</td>
<td>Äpfeln*</td>
</tr>
<tr>
<td>?</td>
<td>Äpfeln?</td>
</tr>
<tr>
<td>+</td>
<td>Äpfeln+</td>
</tr>
<tr>
<td>( )</td>
<td>Sha( la)*</td>
</tr>
<tr>
<td>[ ]</td>
<td>[A-ZÄÖÜ]pfel</td>
</tr>
<tr>
<td>[^ ]</td>
<td>[^ÄÖÜ]pfel</td>
</tr>
<tr>
<td>\</td>
<td>doch\nicht</td>
</tr>
<tr>
<td>s</td>
<td>doch\snicht</td>
</tr>
<tr>
<td>w</td>
<td>Schoko\w*kuchen</td>
</tr>
<tr>
<td>W</td>
<td>Text\W*</td>
</tr>
<tr>
<td>\</td>
<td>100$</td>
</tr>
</tbody>
</table>

Finally, a very useful option to `grep` is `-v`. I'm not sure what the "v" stands for, but in any case `-v` **eliminates** all lines matching the pattern and displays only all others, instead of displaying only those that match. So the `-v` gives us just the opposite behavior – instead of listing all occurrences of the expression, it lists only lines where the expression does not occur. To eliminate all lines that

---

11 Note that CasparHauser.txt is coded in UTF-8, and that Umlaut Ä is only interpreted as one character if you use the UTF-8 encoding in your Terminal. You can change (and query) the encoding of your terminal in the Terminal menu, under "Terminal". You can check the encoding of a file using "file -i", as in

> file -i CasparHauser.txt
contain digits numbers, we could use

```
> grep -v "[0-9]" CasparHauser.txt
```

**sed**

`sed` (short for "stream editor") is a really powerful command which can do all sorts of things. In this tutorial, we will only learn how to use it for substituting strings and regular expressions in its input.

The general syntax for substituting strings or expressions with `sed` is

```
> sed 's/EXPRESSION/REPLACEMENT/' <FILE>
```
or

```
> sed 's/EXPRESSION/REPLACEMENT/g' <FILE>
```

The stuff to be substituted is put between three identical characters – in this case, "/", but we could use any other character that does not appear in the expressions to be substituted. Before specifying these expressions, we put an "s" to indicate that we want to substitute. The two examples above differ in whether they have a "g" at the end of the substitution pattern. The first call replaces only the first occurrence in each line; the second call "greedily" (thus: g) replaces all occurrences.

Here's a more concrete example. We could use `sed` to replace all occurrences of Äpfel or Apfel or Äpfeln in the CasparHauser.txt file by FRUIT:

```
> sed 's/ÄApfeln\?/FRUIT/g' CasparHauser.txt
```

By the way, if you would like to inspect the result without having to scroll for ages, you can pipe the output into a `less` command:

```
> sed 's/ÄApfeln\?/FRUIT/g' CasparHauser.txt | less
```

And then possibly use the search function in `less` to search for the first occurrence of FRUIT (i.e. type "/FRUIT").

A second useful application would be to use `sed` to tokenize a text (i.e., to separate the words at whitespace into a sequence of words, one per line).

```
> sed 's/\s\+/\n/g' CasparHauser.txt
```

Here, and elsewhere in the shell, "\n" is the new line symbol. The "\s" can stand for any space character (see regular expression chart above). So the above command replaces any sequence of one or more whitespace characters by a newline symbol.

If you check the output of the above command, you will see that it produces a
lot of empty lines, in cases where there were several lines containing whitespace characters in a row. We could now pipe the output into a `grep` command and `grep` for lines that actually contain at least one character before the end of the line, which will leave only non-empty lines:\(^{12}\):

\[\textbf{\textgreater{} sed 's/\s\+/\n/g' CasparHauser.txt | grep "." }\]

**sort**

Assume we want to do some statistics over the text in CasparHauser.txt. A useful command is to first sort all words in it alphabetically. To this end, we can use the `sort` command. Its syntax is

\[\textbf{\textgreater{} sort <ONE OR SEVERAL FILES> }\]

It sorts all lines in its input alphanumerically. The input can come either from one or several files, as above, or from standard in, for instance from a pipe.

If you use the -n option, it will sort numerically, and if you use the -r option, it will reverse the sorting order. Thus,

\[\textbf{\textgreater{} sed 's/\s\+/\n/g' CasparHauser.txt | grep "." | sort -r }\]

will sort all words in CasparHauser.txt alphanumerically in descending order, while

\[\textbf{\textgreater{} sed 's/\s\+/\n/g' CasparHauser.txt | grep "^[0-9]" | sort -nr }\]

will sort all tokens that start with a number numerically in descending order.

If you look at all words in CasparHauser.txt sorted alphanumerically, as in

\[\textbf{\textgreater{} sed 's/\s\+/\n/g' CasparHauser.txt | grep "." | sort }\]

you'll notice that there are many identical lines that occur multiple times. If you use option -u (for "unique"), `sort` will print only one of each identical lines. However, if you want to know how many identical lines there were, we'll need to look at yet another simple command called `uniq` to this end.

**uniq**

uniq simply takes its input (from a file or from stdin) and keeps only one of several subsequent identical lines. Note that the identical lines have to be subsequent, i.e. if you have input like this

\[a
b
a\]

\(^{12}\text{And now try to do this in python similarly quickly... :-)\)
nothing will happen, because there are no two identical lines following each other. Thus it is often more interesting to use uniq on already sorted input, such as the output of the commands above:

```
> sed 's/\s\+/\n/g' CasparHauser.txt | grep "." | sort | uniq
```

This should produce the same output as the `sort -u` above. However, uniq provides an option -c (for "count") which prints out the number of identical subsequent lines, resulting in output like this (I'm showing just the first few lines):

```
> sed 's/\s\+/\n/g' CasparHauser.txt | grep "." | sort | uniq -c
  1 
  15 *
  6 ***
  2 *****
  7 –
 14 –
  2 ...
  2 ]
 68 –
  1 ($1
```

This indicates that there were 7 lines with only a "-", 14 with a "->", 2 with "...", etc. Not very nice, I know, because we have left all these punctuation mark symbols that were in the text. But you should be able to figure out how to delete these symbols using sed and \W (You'll be asked to do this in the Exercises section.)

**wc**

Finally, if you would like to know how many word tokens there were in CasparHauser.txt, you can use the wc command. wc counts the number of lines, words, and bytes in its input:

```
> wc CasparHauser.txt
  15941 134785 897580 CasparHauser.txt
```

The first number is the number of lines, the second the number of words, the third the number of bytes. To get only the number of lines, you can provide the -l option

```
> wc -l CasparHauser.txt
  15941
```

The number of words is defined pretty much the way we've done it: it assumes that words are sequences of non-whitespace symbols which are delimited by whitespace symbols. Thus when we "manually" separate the words into lines at sequences of whitespace, using the sed command from above, and then count
the lines, we get the same number as above, 134785:

```bash
> sed 's/\s\+/\n/g' CasparHauser.txt | grep "." | wc -l
134785
```

However, we could decide to "clean up" a bit first, and eliminate lines that don't look like reasonable text using `grep`, and then count again. This would of course give us a better estimate of the length of the text in words.

**Exercises**

1. Give a regular expression to be used by `grep` that describes the following sets of strings
   a) `ab`, `abab`, `ababab`, `abababab`, ...
   b) `aba`, `ababa`, `abababa`, ...
   c) a "gibberish" sentence, which looks like a text from some unknown language, with spaces and punctuation but no numbers or other symbols (something like: Ljsda jgj, qewlu blaj. – be inventive...)

2. Give examples of strings that match
   a) `[A-ZÄÖÜ][a-zäöüß]+`
   b) `[A-Za-z]*`

3. Give a command that would find all lines in file `CasparHauser.txt` that contain `Apfel` either before a whitespace or before the end of the line.

4. Specify a command that would replace all occurrences of "Mann" by "Frau" in the file `CasparHauser.txt`.

5. Specify a command that would count the lines in a file called `file.test`.

6. Which combination of commands would give you the number of occurrences of the word Apfel (i.e. not Apfelbaum!) in `CasparHauser.txt`?

7. Above, we used the command

   ```bash
   sed 's/\s\+/\n/g' CasparHauser.txt | grep "." | sort | uniq -c
   ```

   to count the number of each word token in `CasparHauser.txt`. What would we have to add to delete all non-letter-characters using `sed` before sorting? What would we have to add if we then want to sort by the number of occurrences – i.e., have the most frequent tokens listed last?
Getting Help/Learning more

If you want to learn more about a specific shell command, there is yet another shell command to do so, and that’s the `man` command (short for: manual). So for instance, if you want to know more about the options that the `cp` command can take, you can look at the manual page for `cp` by the `man` command:

```
> man cp
```

This will display an (at first intimidating!) list of all arguments and options to `cp`, plus a description of all its options. Don't worry, most people using the shell are not familiar with all and every option, and it's also not a problem if you only understand a fraction of them. You'll still be able to get at least an idea of what is possible. Check it out some time.
